Occlusion of branches of the ophthalmic artery, resulting in blindness in one or both eyes, is the main complication, occurring in over 25 percent of patients. In the most extreme form, the optic nerve head can be seen to be infarcted, with papilledema and visual loss. This is a form of anterior ischemic optic neuropathy discussed in Chap. 10. In a few cases blindness is preceded by transient visual loss. The sedimentation rate is characteristically elevated above 80 mm/h and sometimes exceeds 120 mm/h, but a small number of cases occur with values below 50 mm/h.

Significant inflammatory involvement of intracranial arteries from temporal arteritis is uncommon, perhaps because of a relative lack of elastic tissue, but in a few cases strokes have occurred on the basis of occlusion of the internal carotid or vertebral arteries.

The diagnosis should be suspected in elderly patients who develop severe, persistent headache and elevation of the sedimentation rate; it depends on finding a tender, thrombosed, or thickened cranial artery and demonstration of the lesion in a biopsy. The procedure is innocuous and the diagnosis may require that both sides be sampled because of the patchy distribution of granulomatous lesions. Schmidt and colleagues have reported that the diagnosis can often be made with duplex ultrasonography. In 22 of 30 cases, a dark halo, probably reflecting edema, surrounded the affected temporal artery; 6 cases showed either occlusion or stenosis of the artery; there were no false-positive tests. A considerable length of the temporal artery can be insonated by this technique, a particularly useful feature in a process that affects the vessel segmentally. From our limited experience, these findings have proven difficult to detect. The arteritic changes may also be revealed by arteriography of the external carotid arteries.

The administration of prednisone, 50 to 75 mg/day, provides striking relief of the headache and polymyalgic symptoms within days and sometimes within hours and also prevents blindness. The medication must be given in very gradually diminishing doses for at least several months or longer, guided by the symptoms and the sedimentation rate. The latter begins to drop within days but seldom falls below 25 mm/h.

Intracranial Granulomatous Arteritis Scattered examples of a small-vessel giant-cell arteritis of undetermined etiology in which only brain vessels are affected have come to medical attention over the years. The clinical state has taken diverse forms, sometimes presenting as a low-grade, nonfebrile meninitis with sterile CSF, followed by infarction of one or several parts of the cerebrum or cerebellum. In other cases it has masqueraded as a cerebral tumor, evolving over a period of weeks, or as a viral encephalitis or an unusual dementia. Headaches (variable in our experience but sometimes severe), focal cerebral or cerebellar signs of gradual (seldom stroke-like) evolution, confusion with memory loss, pleocytosis and elevated CSF protein, and papilledema as a result of increased intracranial pressure (in about half the cases) constitute the most frequently encountered syndrome. The symptoms usually persist for several months. In contrast to temporal arteritis, the sedimentation rate is generally normal or only slightly elevated.

In only about half the patients can the diagnosis be made by angiography, which demonstrates an irregular narrowing and in some cases blunt ending of small cerebral arteries (Fig. 34-31). CT scanning and MRI show multiple irregular white matter and cortical changes and small cortical lesions; often these cannot be differentiated from a tumor or infectious process. Occasionally the white matter abnormalities become confluent and the radiologic appearance simulatesBinswanger disease or hypertensive encephalopathy. The diagnosis is made most often by a brain biopsy, which includes a sample of the meninges, but even with tissue sampling, only about half of suspected cases show the typical histopathologic changes; often, however, patients with normal angi-
Takayasu Disease (Aortic Branch Disease, Occlusive Thromboaortopathy) This is a nonspecific arteritis involving mainly the aorta and the large arteries arising from its arch. It is similar in many ways to giant-cell arteritis except for its propensity to involve the proximal rather than the distal branches of the aorta. Most of the patients have been young Asian women, but there are scattered reports of similar cases from the United States, Latin America, and eastern Europe. The exact etiology has never been ascertained, but an autoimmune mechanism is suspected.

Constitutional symptoms such as malaise, fever, anorexia, weight loss, and night sweats usually introduce the disease. The erythrocyte sedimentation rate is elevated in the early and active stages. Later there is evidence of occlusion of the innominate, subclavian, carotid, vertebral, and other arteries. The affected arteries no longer pulsate, hence the descriptive term pulseless disease. However, it should be noted that in non-Asian individuals, the disease is usually due to atherosclerosis. When renal arteries are involved, hypertension may result, and there may be coronary occlusion. When the aorta is eroded, with spread of granuloma to the cranial cavity and more remote parts. Cerebrovascular events, seizures, and cerebritis are less common neurologic complications. Spastic paraparesis, temporal arteritis, Horner syndrome, and papilledema have been observed but are rare (see Nishino et al). The orbits are involved in 20 percent of patients, and lesions here simulate the clinical and radiologic appearance of orbital pseudotumor, cellulitis, or lymphoma. Pulmonary granulomas, usually asymptomatic but evident on a chest film, are also common. The vasculitis implicates both small arteries and veins. There is a fibrinoid necrosis of their walls and an infiltration by neutrophils and histiocytes. The sedimentation rate is elevated, as are the rheumatoid and antiglobulin factors. The presence in the blood of antineutrophil cytoplasmic antibodies (c–ANCA) has been found to be relatively specific and sensitive for Wegener disease but it may also be present in intravascular lymphoma.

A degree of therapeutic success in this formerly fatal disease has been achieved by the use of cyclophosphamide, chlorambucil, or azathioprine. Cyclophosphamide in oral doses of 1 to 2 mg/kg per day has cured 90 to 95 percent of the cases. In acute cases, rapidly acting steroids—prednisone, 50 to 75 mg/day — should be given in conjunction with the immunosuppressant drug(s).
Systemic Lupus Erythematous

Involvement of the nervous system is an important aspect of this disease. In the pathologic and clinical series reported by Johnson and Richardson, the CNS was affected in 75 percent of cases, but our recent experience has suggested a far lower frequency of clinical manifestations. Disturbances of mental function—including alteration of consciousness, seizures, and signs referable to cranial nerves—are the usual neurologic manifestations; most often they develop in the late stages of the disease, but they may occur early and may be mild and transient. Hemiparesis, paraparesis, aphasia, homonymous hemianopia, movement disorders (chorea), and derangements of hypothalamic function occur but have been infrequent in our experience. Larger infarcts are usually traceable to emboli from Libman-Sacks (nonbacterial thrombotic, marantic) endocarditis. In some instances the CNS manifestations resemble multiple sclerosis, especially when there is an optic neuritis and myelopathy. The presence of serum antinuclear antibodies is of help in the differentiation of lupus erythematous but in itself does not establish the diagnosis. The CSF is entirely normal or shows only a mild lymphocytic pleocytosis and increase in protein content, although in some patients—primarily those with peripheral neuropathy and myelopathy—the protein content may be greatly increased.

Most of the neurologic manifestations can be accounted for by widespread microinfarcts in the cerebral cortex and brainstem; these, in turn, are related to destructive and proliferative changes in arterioles and capillaries. The acute lesion is subtle; it is not a typical fibrinoid necrosis of the vessel wall, like that in hypertensive encephalopathy, and there is no cellular infiltration. Attachment of immune complexes to the endothelium is the postulated mechanism of vascular injury. Thus, the changes do not represent a vasculitis in the strict sense of the word. Other neurologic manifestations are related to hypertension, which frequently accompanies the disease and may precipitate cerebral hemorrhage; to endocarditis, which may give rise to cerebral embolism; to thrombotic thrombocytopenic purpura, which commonly complicates the terminal phase of the disease (Devinsky et al); and to treatment with corticosteroids, which may precipitate or accentuate muscle weakness, seizures, and psychosis. In other cases, steroids appear to improve these neurologic manifestations. A similar set of neurologic problems arises in relation to the anti–phospholipid antibody phenomenon. Often it is associated with an allergic skin lesion (Stevens-Johnson vasculopathy or a leukocytoclastic vasculitis). The clinical picture does not resemble that of polyarteritis nodosa, but the central or peripheral nervous system is affected in rare instances. The response to corticosteroids is excellent.

Yet another ill-defined form of vasculitis has been described by Susac and colleagues (Susac syndrome). This is a microangiopathy affecting mainly the brain and retina. Psychiatric symptoms, dementia, sensorineural deafness, and impairments of vision are the clinical manifestations. Funduscopy (multiple retinal artery branch occlusions) and arteriography manifest evidence of the vasculopathy. The patients seem to respond to steroid therapy. Only biopsy material has been examined.

Mixed essential cryoglobulinemia, a vasculitic disorder that more often affects the peripheral than the central nervous system, may nonetheless produce an encephalopathy.

Behçet Disease

This disorder may suitably be considered here, since it is essentially a chronic, recurrent vasculitis, involving small vessels, with prominent neurologic manifestations. It is most common in Turkey, where it was first described, in other Near Eastern countries, and in Japan, but it occurs throughout Europe and North America, affecting men more often than women. The disease was originally distinguished by the triad of relapsing iridocyclitis and recurrent oral and genital ulcers, but it is now recognized to be a systemic disease with a much wider range of symptoms, including
erythema nodosum, thrombophlebitis, polyarthritis, ulcerative colitis, and a number of neurologic manifestations, some of them encephalitic or meningitic in nature. The most reliable diagnostic criteria, according to the International Study Group that assembled data on 914 cases from 12 medical centers in 7 countries, were recurrent aphthous or herpetiform oral ulceration, recurrent genital ulceration, anterior or posterior uveitis, cells in the vitreous or retinal vasculitis, and erythema nodosum or papulopustular lesions.

The nervous system is affected in about 30 percent of patients with Behçet disease (Chajek and Painaru); the manifestations are: recurrent meningoecephalitis, cranial nerve (particularly abducens) palsies, cerebellar ataxia, and corticospinal tract signs. There may be episodes of diencephalic and brainstem dysfunction resembling minor strokes. A few postmortem examinations have related these small foci of necrosis to a vasculitis, including perivascular and meningeal infiltration of lymphocytes. There may also be cerebrovascular thrombosis. The neurologic symptoms usually have an abrupt onset and are accompanied by a brisk spinal fluid pleocytosis (lymphocytes or neutrophils may predominate), along with elevated protein but normal glucose values (in one of our patients, 3000 neutrophils per cubic millimeter were found at the onset of an acute meningitis). As a rule, neurologic symptoms clear completely in several weeks, but they have a tendency to recur, and some patients are left with persistent neurologic deficits. Rarely, the clinical picture is that of a progressive confusional state or dementia (see the reviews of Alema and of Lehner and Barnes for detailed accounts).

The cause of Behçet disease is unknown. We have been unable to detect virus particles in the margins of an ulcerative mouth lesion. A pathergy skin test—the formation of a sterile pustule at the site of a needle prick—is listed as an important diagnostic test by the International Study Group, but on the basis of admittedly limited U.S. experience, we and our colleagues have found it to be of questionable value. Administration of corticosteroids has been the usual treatment, on the assumption of an autoimmune etiology. Since the episodes of disease naturally subside and recur, evaluation of treatment is difficult.

THROMBOSIS OF CEREBRAL VEINS AND VENOUS SINUSES

Thrombosis of the cerebral venous sinuses, particularly of the superior sagittal or lateral sinuses and the tributary cortical and deep veins, gives rise to a number of important neurologic syndromes. Cerebral vein thrombosis may develop in relation to infections of the adjacent ear and paranasal sinuses or to bacterial meningitis, as described in Chap. 32. More common is noninfectious venous occlusion resulting from one of the many hypercoagulable states discussed below.

Occlusion of cortical veins that are the tributaries of the dural sinuses takes the form of a venous infarctive stroke. The diagnosis is difficult except in certain clinical settings known to favor the occurrence of venous thrombosis, such as the taking of birth control pills or postpartum and postoperative states, which are often characterized by thrombocytosis and hyperfibrinogenemia. Hypercoagulable conditions also occur in cancer (particularly of the pancreas and other abdominal organs), cyanotic congenital heart disease; cachexia in infants; sickle cell disease; antiphospholipid antibody syndrome, the aforementioned Behçet disease, factor V Leiden mutation, protein S or C deficiency, antithrombin III deficiency, resistance to activated protein C; primary or secondary polycythemia and thrombocytethemia; and paroxysmal nocturnal hemoglobinuria. The study by Martinelli and colleagues, mentioned earlier in the chapter, attributed 35 percent of cases of cerebral vein thrombosis to a mutation in the factor V or the prothrombin gene. Averback, who reported seven cases of venous thrombosis in young adults, has emphasized the diversity of the clinical causes. Two of his patients had carcinoma of the breast and one had ulcerative colitis. A few cases will follow head injury or remain unexplained.

A stroke in a patient suffering from any one of these systemic conditions should suggest venous thrombosis, though in some instances—e.g., postpartum strokes—arteries are occluded as often as veins. The somewhat slower evolution of the clinical stroke syndrome, the presence of multiple cerebral lesions not in typical arterial territories, and its greater epileptogenic and hemorrhagic tendency favor venous over arterial thrombosis.

Superficial Thrombosis of Cortical Veins Certain syndromes occur with sufficient regularity that they suggest thrombosis of a particular vein or sinus. The signature features of isolated thrombosis of superficial cortical veins are the presence of large superficial (cortex and subjacent white matter) hemorrhagic infarctions and a marked tendency to partial seizures. Hemiparesis, incomplete hemianopia, and aphasia, any of which may fluctuate over days, are also characteristic according to Jacobs and colleagues. These variable syndromes reflect the inconstant location of the main surface veins. Thrombosis of the vein of Labbé causes infarction of the underlying superior temporal lobe, and occlusion of the vein of Trolard implicates the parietal cortex. Quite often, in our experience, the focal deficit worsens immediately after a partial seizure. The intracranial pressure is not elevated, as it is when the dural venous sinuses are occluded. The diagnosis is now made by careful examination of the MR venogram or by the venous phase of the conventional angiogram. Cortical vein thrombosis should be suspected in the situation of multiple hemorrhagic infarctions in one hemisphere without a source of embolism or atherothrombosis.

Dural Sinus Thrombosis

Sagittal and Lateral Sinus Thrombosis In the case of sagittal sinus thrombosis, intracranial hypertension with headache, vomiting, and papilledema may constitute the entire syndrome (this is the main consideration in the differential diagnosis of pseudotumor cerebri, Chap. 30) or it may be conjoined with hemorrhagic infarction. Paraparesis, hemiparesis, fluctuating unilateral or bilateral sensory symptoms, or aphasia result only if the thrombosis propagates to surface veins. Focal or odd sensory or motor seizures occur on the same basis but are not as common as with cortical vein thrombosis.

The common radiologic picture that results from occlusion of the superior sagittal sinus is of bilateral superficial paramedian parietal or frontal hemorrhagic infarction or edematous venous congestion. In the case of CT scan with contrast infusion, a lack of dye opacification in the posterior sagittal sinus can be observed with careful adjustment of the viewing window (“empty delta sign”). The spinal fluid pressure is increased and the fluid may be slightly sanguineous. Lateral sinus thrombosis causes hemorrhagic infarction of the temporal lobe convexity, usually with considerable vasogenic edema. The enhanced CT scan, arteriography (venous phase), and MR venography greatly facilitate diagnosis by directly visualizing the venous occlusion. Once a venous thrombosis be-
comes established, the tributary surface veins take on a “corkscrew” appearance that is appreciated on the venous phase of an angiogram.

**Cavernous Sinus Thrombosis** As pointed out in Chaps. 13 and 14, in cases of *anterior cavernous sinus thrombosis* there is marked chemosis and proptosis—with disorders referable to cranial nerves III, IV, VI, and the ophthalmic division of V (Fig. 34-32). *Posterior cavernous sinus thrombosis*, spreading to the inferior petrosal sinus, may cause palsies of cranial nerves VI, IX, X, and XI without proptosis, and involvement of the *superior petrosal sinus* may be accompanied by a fifth nerve palsy. Increased intracranial pressure without ventricular dilatation occurs with thrombosis of the superior sagittal sinus, the main jugular vein, and the lateral sinus or torcular.

Thrombosis of the venous sinuses in neonates presents special problems in diagnosis. In the series of deVeber et al, various perinatal complications, including systemic illness such as severe dehydration or infection, were the common precedents; the outcome was poor. In young children the risk factors differed in that connective tissue and prothrombotic disorders and head and neck infections were more common.

**Deep Cerebral Vein Thrombosis** Occlusion of the vein of Galen and of the internal cerebral veins is the rarest and clinically most obscure of the venous syndromes. From the few cases that have been studied, a picture of bithalamic infarction emerges, often reversible, and consisting mainly of inattention, spatial neglect, and amnesia in the case reported by Benabdeljili and colleagues and of akinetic mutism and apathy in the case of Gladstone and associates. In most reports of this condition, it is the neuropsychological aspects that are emphasized. The MRI is striking, with a large bicircular region of signal change that encompasses the thalami. Much of the signal change probably represents reversible edema and venous congestion, since substantial clinical improvement may occur.

**Treatment of Cerebral Venous Thrombosis** Anticoagulant therapy beginning with heparin for several days, followed by warfarin, and combined with antibiotics if the venous occlusion is infectious (it rarely is in recent times) has been lifesaving in some cases. Nonetheless, the overall mortality rate remains high, with large hemorrhagic venous infarctions found in 10 to 20 percent of cases. The clinical trial conducted by Einhaupl and colleagues has settled the question of therapy in favor of aggressive anticoagulation.

Thrombolytic therapy by local venous or systemic infusion has also been successful in small series of cases, such as the 5 patients treated with urokinase and heparin by DiRocco and colleagues. However, this approach has not been subjected to a systematic study. We have reserved thrombolysis for extreme cases of dural sinus thrombosis with stupor or coma and greatly raised CSF pressure. This subject is reviewed by Benamer and Bone, who conclude that warfarin anticoagulation should be reserved for patients who deteriorate despite treatment with heparin. Most treated patients do well, but it may take weeks for the headaches to remit. Coma and multiple cerebral hemorrhages, on the other hand, are usually fatal.

**Nonbacterial Thrombotic (Marantic) Endocarditis and Cerebral Embolism**

Sterile vegetations, referred to also as *nonbacterial thrombotic endocarditis*, consist of fibrin and platelets and are loosely attached to the mitral and aortic valves and contiguous endocardium. They are a common source of cerebral embolism (almost 10 percent of all instances of cerebral embolism according to Barron et al, but lower in the experience of others). In almost half the patients, the vegetations are associated with a malignant neoplasm; the remainder occurs in patients debilitated by other diseases (Biller et al). Except for the setting in which it occurs, marantic embolism has no distinctive clinical features that permit differentiation from cerebral embolism of other types other than that it is often the cause of sequential strokes over days or weeks. The apoplectic nature of marantic embolism distinguishes it from the usual forms of tumor metastases. The hazards of using anticoagulants in gravely ill patients with widespread malignant disease probably outweigh the benefits from this treatment, but drugs that prevent platelet aggregation, while possibly helpful, have not been studied systematically for this condition.

The lesions of small cerebral arteries formerly observed in patients with rheumatic heart disease and referred to as *rheumatic arteritis* have not been well characterized clinically or pathologically. The vascular lesions and the microinfarcts that accompany them are probably manifestations of diffuse cerebral embolism. There is probably no relationship to the lesion of Sydenham chorea.

**Stroke as a Complication of Hematologic Disease**

The brain is involved in the course of many hematologic disorders, some of which have already been mentioned. A number of the better-characterized ones are discussed here.

**Antiphospholipid Antibody Syndrome** This condition, in which T1As, or stroke, migraine, and thrombocytopenia in various combinations, occurs in young adults, has already been mentioned under “Strokes in Children and Young Adults.” The related term

![Figure 34-32. Diagram of the cavernous sinus: (1) optic chiasm; (2) oculomotor nerve; (3) cavernous sinus; (4) trochlear nerve; (5) internal carotid artery; (6) ophthalmic nerve; (7) abducens nerve; (8) maxillary nerve. (Reproduced by permission from Krayenbühl and Yasargil.)](image-url)
The most frequent neurologic abnormality is a TIA, usually taking the form of amaurosis fugax (transient monocular blindness), with or without retinal arteriolar or venous occlusion (Digre et al). Stroke-like phenomena are more frequent in patients who also have migraine, hyperlipidemia, and antinuclear antibodies and in those who smoke or take birth control pills. Almost one-third of the 48 patients reported by Levine and associates had thrombocytopenia and 23 percent had a false-positive VDRL test. Some of the phospholipids with which the antibodies react are shared with clotting factors, particularly prothrombin and annexin, as well as with the “lupus anticoagulant” (a cardiolipin-glycoprotein complex). These antibodies are circulating serum polyclonal immunoglobulins (IgG, IgM, IgA). The vascular lesions are mainly in the cerebral white matter and are infarcts, seen well with MRI. Angiography reveals occlusions of arteries at unusual sites (Brey et al). The mechanism of stroke is not entirely clear and may derive from emboli originating on mitral valve leaflets similar to nonbacterial thrombotic endocarditis; alternatively, and more likely in our view, there is a noninflammatory in situ thrombosis of medium-sized cerebral vessels, as suggested by the limited pathologic material studied by Briley and colleagues.

These circulating antibodies may also cause a syndrome of transient bilateral choreal or hemichorea; some patients have an additional slight hemiparesis or other subtle focal signs. Almost all of the affected patients we have seen have been women with thrombocytopenia, some of whom probably had systemic lupus, at least on the grounds of laboratory studies (see Cevera et al). A direct connection of the choreic syndrome to the antibodies, comparable to what is proposed in Sydenham chorea, may be valid but at the moment is unproven. Some cases display microinfarctions in the basal ganglia, perhaps on the basis of valvular vegetations. The syndrome may be precipitated in these patients by the introduction of estrogen-containing birth control pills and is improved, usually promptly, by corticosteroids or antiplatelet agents.

The Sneddon syndrome consists of deep blue-red lesions of livedo reticularis and livedo racemosa in association with multiple strokes; 126 cases had been reported up to 1992. Most but not all patients have high titters of antiphospholipid antibodies. Although the skin lesions show a noninflammatory vasculopathy with intimal thickening, the pathology of the occlusive disease has not been adequately studied. In a report of 17 such patients by Stockhammer and coworkers, 8 had strokes and MRI showed lesions in 16 of 17 patients. The age of patients with strokes was 30 to 35 years, hence this condition must always be considered in young adults with cerebrovascular disease. Many of the lesions on MRI were small, deep, and multiple. Although there is a tendency for strokes to recur, many of the patients have remained well for years after a single stroke. Skin biopsy aids in diagnosis.

There are instances in which the radiologic changes caused by recurrent small infarctions are difficult to distinguish from multiple sclerosis, as discussed in several parts of Chap. 36, on demyelinating diseases. Associations of the syndrome with transverse myelitis, Guillain-Barré syndrome, hearing loss, and a number of other processes has been suspected but not proven.

**Treatment** Warfarin has been used with some benefit in the above conditions. Khamashta and colleagues have found that the INR must be maintained close to 3 for effective prevention of stroke. According to the study conducted by Crowther and colleagues, an INR of 2 to 3 conferred the same degree of protection from thrombosis as did higher levels, but the number of thrombotic events was low in both groups and there was only one stroke in 114 patients over a period of about 3 years. Patients with severe thrombocytopenia and with other intrinsic coagulopathies should be treated with warfarin very cautiously. Although the INR is used as a gauge of the level of anticoagulation, it may be altered by the antibodies; no ideal method for monitoring treatment has been devised. Aspirin, on uncertain grounds, is thought not to confer protection for stroke, but in only a few small series has its effect been analyzed. In “catastrophic” cases, intravenous immunoglobulin and plasma exchange have been used with some effect.

It is most important to eliminate smoking and estrogen-containing compounds, since these greatly raise the risk of stroke. Plasma exchange may be useful in fulminant cases. Aspirin and heparin are favored in women with recurrent fetal loss related to antiphospholipid antibody (Lockshin and Sammaritano).

**Thrombotic Thrombocytopenic Purpura (TTP, Moschcowitz Syndrome)** This is yet another uncommon but serious disease of the small blood vessels, observed mainly in young adults. It is characterized pathologically by widespread occlusions of arterioles and capillaries involving practically all organs of the body, including the brain, as described by Adams and colleagues (1948). The nature of the occluding material has not been completely defined. Fibrin components have been identified by immunofluorescent techniques; some investigators have demonstrated disseminated intravascular platelet aggregation rather than fibrin thrombi. TTP is caused by an acquired circulating IgG inhibitor of von Willebrand factor—cleaving protease; a rarer familial form is caused by a constitutional deficiency of the protease.

Clinically, the main features of this disease are fever, anemia, symptoms of renal and hepatic disease, and thrombocytopenia—the latter giving rise to the common hemorrhagic manifestations (petechiae and ecchymoses of the skin, retinal hemorrhages, hematuria, gastrointestinal bleeding, etc.). Neurologic symptoms are practically always present and are the initial manifestation of the disease in about half the cases. Confusion, delirium, seizures, and hemiparesis—sometimes remittent or fluctuating in nature—are the usual manifestations of the nervous system disorder and are readily explained by the widespread microscopic ischemic lesions in the brain. Garrett and colleagues have emphasized the presentation of nonconvulsive status epilepticus in TTP, and we have encountered two such cases. Gross infarction was not observed. In most patients who survive, recovery of the focal neurologic deficits can be expected unless there is an identifiable infarction on CT or MRI. The CSF is normal except for elevated protein in some cases. To our knowledge, a mononeuritis multiplex does not occur. The recommended treatment is plasma exchange or plasma infusion.
Thrombocytosis and Thrombocythemia These terms refer to an increase of platelets above 800,000/mm³. The condition is generally considered to be a form of myeloproliferative disease. In some patients there is an enlarged spleen, polycythemia, chronic myelogenous leukemia, or myelosclerosis. In several of our patients no explanation of the thrombocytosis was found. They presented with recurrent cerebral and systemic thrombotic episodes, often of minor degree and transient. Cytopheresis, to reduce the platelets, and antimitotic drugs (hydroxyurea) to suppress megakaryocyte formation, are helpful in ameliorating the neurologic symptoms. In one of the cases we have followed, several small lesions, presumably infarctions, were situated in the white matter and simulated multiple sclerosis.

Polycythemia Vera This is another myeloproliferative disorder of unknown cause, characterized by a marked increase in RBC mass and in blood volume and often by an increase in WBCs and platelets as well. This condition must be distinguished from the many secondary or symptomatic forms of polycythemia (erythrocytosis), in which the platelets and white cells remain normal. The slightly increased incidence of thrombosis in primary polycythemia is attributed to the high blood viscosity, engorgement of vessels, and reduced rate of blood flow. The majority of patients with cerebrovascular manifestations have TIA's and small strokes, but we have seen one case of sagittal sinus thrombosis. With very high hematocrit, sludging of red cells may be seen in the retinal vessels. The cause of cerebral hemorrhage in this disease is less clear, although a number of abnormalities of platelet function and of coagulation have been described (see Davies-Jones et al).

A wide variety of bleeding disorders—such as leukemia, aplastic anemia, thrombocytopenic purpura, and hemophilia—may also give rise to cerebral hemorrhage. Many rare forms of bleeding disease may be complicated by hemorrhagic manifestations; these have been reviewed by Davies-Jones and colleagues.

Sickle Cell Disease This inherited disease is related to the presence of the abnormal hemoglobin S in the red corpuscles. Clinical abnormalities occur only in patients with sickle cell disease—i.e., with the homozygous state, and not in those with the sickle cell trait, which represents the heterozygous state. The disease, which is practically limited to persons of central African and certain Mediterranean origins, begins early in life and is characterized by “cries” of infection (particularly pneumococcal meningitis), pain in the limbs and abdomen, chronic leg ulcers, and infarctions of bones and visceral organs. Ischemic lesions of the brain, both large and small, are the most common neurologic complications, but cerebral, subarachnoid, and subdural hemorrhage may also occur and the vascular occlusions may be either arterial or venous.

Disseminated Intravascular Coagulation (DIC) This is perhaps the commonest and most serious disorder of coagulation affecting the nervous system. The basic process depends on the release of thromboplastin from damaged tissue, resulting in the activation of the coagulation process and the formation of fibrin, in the course of which clotting factors and platelets are consumed. Virtually any mechanism that produces tissue damage can result in the release of tissue thromboplastins into the circulation. Thus, DIC complicates a wide variety of clinical conditions—overwhelming sepsis, massive trauma, cardiothoracic surgery, heat stroke, burns, incompatible blood transfusions and other immune complex disorders, diabetic ketoacidosis, leukemia, obstetric complications, cyanotic congenital heart disease, and shock from many causes.

The essential pathologic change in DIC is the occurrence of widespread fibrin thrombi in small vessels, resulting in numerous small infarctions of many organs, including the brain. Sometimes DIC is manifest by a hemorrhagic diathesis in which petechial hemorrhages are situated around small penetrating vessels. In some cases cerebral hemorrhage is quite extensive, similar to a primary hypertensive hemorrhage. The main reason for the hemorrhage is the consumption of platelets and various clotting factors that occurs during fibrin formation; in addition, fibrin degradation products have anticoagulant properties of their own.

The diffuse nature of the neurologic damage may suggest a metabolic rather than a vascular disorder of the brain. In the absence of a clear metabolic, infective, or neoplastic cause of an encephalopathy, the onset of acute and fluctuating focal neurologic abnormalities or a generalized and sometimes terminal neurologic deterioration during the course of a severe illness should arouse suspicion of DIC, and coagulation factors and fibrin split products should be measured. Platelet counts are invariably depressed and there is evidence of consumption of fibrinogen and other clotting factors, indicated by prolonged prothrombin and partial thromboplastin times.

In the related illness abbreviated as HELLP mentioned previously, women with eclampsia develop liver failure and thrombocytopenia; the contribution of this limited form of DIC to the eclamptic effects on the nervous system have not been established (see earlier discussion of eclampsia).

DIFFERENTIATION OF VASCULAR DISEASE FROM OTHER NEUROLOGIC ILLNESSES

The diagnosis of a vascular lesion rests essentially on recognition of the stroke syndrome; without evidence of this, the diagnosis must always be in doubt. The three criteria by which the stroke is identified should be re-emphasized: (1) the temporal profile of the clinical syndrome, (2) evidence of focal brain disease, and (3) the clinical setting. Definition of the temporal profile requires a clear history of the premonitory phenomena, the mode of onset, and the evolution of the neurologic disturbance in relation to the patient’s medical status. Here, an inadequate history is the most frequent cause of diagnostic error. If these data are lacking, the stroke profile may still be determined by extending the period of observation for a few days or weeks, thus invoking the clinical rule that the physician’s best diagnostic tool is a second and third examination.

There are few categories of neurologic disease whose temporal profile mimics that of the cerebrovascular disorders. Migraine may do so, but the history usually provides the diagnosis. A seizure may be followed by a prolonged focal deficit (Todd’s paralysis) but is rarely the initial event in a stroke; the setting in which these symptoms occur and their subsequent course clarify the clinical situation. Stroke-like episodes appear in the course of certain hereditary metabolic disorders (Fabry disease, homocystinuria, mitochondrial disease). Differentiation is not difficult because of the associated myopathic and neurologic signs and characteristic metabolic defects. Tumor, infection, inflammation, degeneration, and nutritional deficiency are not likely to manifest themselves precipitously, although rarely a brain metastasis produces a focal deficit of abrupt onset (see below). Trauma, of course,
occurs abruptly but usually offers no problem in diagnosis. In multiple sclerosis and other demyelinating diseases, there may be an abrupt onset or exacerbation of symptoms, but for the most part they occur in a different age group and clinical setting. Conversely, a stroke-like onset of cerebral symptoms in a young adult should always raise a suspicion of demyelinating disease. A stroke developing over a period of several days usually progresses in a stepwise fashion, increments of deficit being added abruptly from time to time. A slow, gradual, downhill course over a period of 2 weeks or more indicates that the lesion is probably not vascular but rather neoplastic, demyelinating, infectious (abscess) or granulomatous, or a subdural hematoma.

In regard to the focal neurologic deficits of cerebrovascular disease, many of the nonvascular diseases may produce symptoms that are much the same, and the diagnosis cannot rest solely on this aspect of the clinical picture. Nonetheless, certain combinations of neurologic signs, if they conform to a neurovascular pattern—e.g., the lateral medullary syndrome—mark the disease as vascular in nature.

Many thrombotic strokes are preceded by TIAs, which, if recognized, are diagnostic of this form of vascular disease. It is essential that TIAs be differentiated from seizures, syncope, panic attacks, neurologic migraine, and attacks of labyrinthine vertigo, since a failure to do so may result in unnecessary arteriographic studies and even a surgical operation.

With very few exceptions, the presence of blood in the CSF points to a cerebrovascular (rarely spinal vascular) lesion provided that trauma and a traumatic tap can be excluded. Headache is common in cerebrovascular disease; it occurs not only with hemorrhage but also with thrombosis, arterial dissections, and rarely with embolism. Seizures are almost never the premonitory, first, or only manifestation of a stroke but can rarely occur in the first few hours after infarction or intracranial bleeding. Brief unconsciousness (5 to 10 min) is rare in stroke, being seen only with basilar artery insufficiency and as an initial event in ruptured aneurysm or primary intracerebral hemorrhage. In the latter case, a depression in the state of consciousness soon reasserts itself and is then progressive. Certain neurologic disturbances are hardly ever attributable to stroke—e.g., diabetes insipidus, fever, bitemporal hemianopia, parkinsonism, generalized myoclonus, repeated falls, and isolated cranial nerve palsies—and their presence may be of help in excluding vascular disease.

Finally, the diagnosis of cerebrovascular disease should always be made on positive data, not by exclusion.

A few conditions are so often confused with cerebrovascular diseases that they merit further consideration. When a history of trauma is absent, the headache, drowsiness, mild confusion, and hemiparesis of subdural hematoma may be ascribed to a “small stroke,” and the patient may fail to receive immediate surgical therapy. In subdural hematoma, the symptoms and signs usually develop gradually over a period of days or weeks. The degree of headache, obtundation, and confusion is disproportionately greater than the focal neurologic deficit, which tends to be indefinite and variable until late in the evolution of the hematoma. If the patient has fallen and injured his head at the onset of the stroke, it may be impossible to rule out a complicating subdural hematoma on clinical grounds alone, in which case CT scanning and MRI are usually diagnostic. The reverse diagnostic error will not be made if one remembers that patients with subdural hematoma rarely exhibit a total hemiplegia, monoplegia, hemianesthesia, homonymous hemianopia, or aphasia. If such focal signs are present and particularly if they developed suddenly, subdural hematoma is not likely to be the explanation.

A brain tumor, especially a rapidly growing glioblastoma multiforme or lymphoma, may produce a severe hemiplegia within a week or two. Also, the neurologic deficit due to carcinoma metastatic to the cerebrum may evolve rapidly, almost at a stroke-like pace. Moreover, in rare cases, the hemiplegia may be preceded by transitory episodes of neurologic deficit, indistinguishable from TIAs. However, in both conditions, a detailed history will indicate that the evolution of symptoms was gradual; if it was saltatory, seizures will usually have occurred. The chest film frequently discloses a primary or secondary tumor, and an increased blood sedimentation rate suggests that a concealed systemic disease process is at hand. A lack of detailed history may also be responsible for the opposite diagnostic error, i.e., mistaking a relatively slowly evolving stroke (usually due to internal carotid artery or basilar occlusion) for a tumor. Again, CT scanning and MRI will usually settle the problem. A brain abscess or inflammatory necrotic lesion—e.g., herpes encephalitis or toxoplasmosis—may also develop rapidly.

Dementia of the Alzheimer type is often ascribed, on insufficient and conceptually incorrect grounds, to the occurrence of multiple small strokes. If vascular lesions are responsible, evidence of an apoplectic episode or episodes and of focal neurologic deficit to account for at least part of the syndrome will almost invariably be disclosed by history and examination. In the absence of a history of episodic development or of focal neurologic signs, it is unwaranted to attribute senile dementia to cerebrovascular disease—in particular to small strokes in silent areas. Cerebral arteriosclerosis is another term that has often been used carelessly to explain such mental changes, the implication (incorrect) being that arteriosclerosis itself causes ischemic damage to the nervous system, producing loss of intellectual function but no other neurologic deficit. If cerebral arteriosclerosis (atherosclerosis) is actually responsible, there should be evidence of it in the form of strokes at some time in the course of the illness and often in the heart (myocardial infarction, angina pectoris) or legs (intermittent claudication, loss of pulses). Frequently the lesions of both vascular and Alzheimer disease are present, in which case there may be difficulty in determining to what extent each of them is responsible for the neurologic deficit. Several studies have shown an increased incidence or an acceleration of Alzheimer dementia if there are concurrent vascular lesions, but further studies are needed to confirm this notion.

Recurrent seizures as the result of a previous stroke occur in up to 10 percent of cases (postinfarction epilepsy, page 740). When evidence, by history or examination, of the original stroke is lacking, as it often is, or if the seizures are not observed or leave behind a temporary increase in the neurologic deficit (Todd’s paralysis), the diagnosis of another stroke or a tumor may be made in error.

Miscellaneous conditions occasionally taken to be a stroke are Bell’s palsy; Stokes-Adams attacks; a severe attack of labyrinthine vertigo; diabetic ophthalmoplegia; acute ulnar, radial, or peroneal palsy; embolism to a limb; and temporal arteritis associated with blindness.

Contrariwise, certain manifestations of stroke may be incorrectly interpreted as evidence of some other neurologic disorder. In lateral medullary infarction, dysphagia may be the outstanding feature; if the syndrome is not kept in mind, a fruitless radiologic search for a local esophageal or pharyngeal cause may be undertaken. Similarly, facial pain or a burning sensation due to involvement of the trigeminal spinal nucleus in lateral medullary stroke may be misattributed to sinus disease. Headache, at times severe,
often occurs as a prodrome of a thrombotic stroke or subarachnoid hemorrhage; unless this is appreciated, a diagnosis of migraine may be made. Dizzy spells, vertigo, vomiting, or brief intermittent lapses of equilibrium due to vascular disease of the brainstem may be ascribed to vestibular neuronitis, Ménière disease, Stokes-Adams syncope, or gastroenteritis. A detailed account of the attack will usually avert this error. A strikingly focal monoplegia of cerebral origin, causing only weakness of the hand or arm or foot drop, is not infrequently misdiagnosed as a peripheral neuropathy.

In the presence of coma, the differentiation of vascular from other neurologic diseases offers special problems. If the patient is comatose when first seen and an adequate history is not available, cerebrovascular lesions must be differentiated from all the other causes of coma described in Chap. 17 and commented on below.

COMMON CLINICAL PROBLEMS IN CEREBROVASCULAR DISEASE

Inevitably, most patients are seen first by clinicians who may not be expert in all the fine points of cerebrovascular disease. Situations arise in which critical decisions must be made regarding anticoagulation, further laboratory investigation, and the advice and prognosis to be given to the family. The following are some of the situations encountered by the authors that may be of value to students and residents and to nonspecialists in the field.

The Patient with a History of an Ischemic Attack or Small Stroke in the Past The patient may be functioning normally when examined, but it has been ascertained by the history or radiologic procedures that a stroke or TIA occurred in the past. The problem is what measures should be taken to reduce the risk of further strokes. This is particularly problematic if a surgical procedure is planned. A brief focal TIA, several minutes or less in duration, or many stereotyped spells usually represent severe stenosis of the internal carotid artery on the side of the affected cerebral hemisphere. If the symptoms have occurred recently, these may be forerunners of complete occlusion. If the TIA was far in the past—more than several weeks previously—the immediate risks of occlusion are reduced. The initial approach is to establish the patency of the carotid arteries by ultrasound or MRA. If there is a reduction in diameter of greater than 70 percent when compared with an adjacent normal segment of vessel, and probably if there is a severely ulcerated but not critically stenotic plaque, carotid surgery (or angioplasty) is advisable. If a single TIA lasted more than an hour or the neurologic examination discloses minor signs referable to the region of the hemisphere affected by the TIA, a search for a source of embolus is indicated. Appropriate diagnostic studies include ECG, a transesophageal echocardiogram, monitoring for cardiac arrhythmia, ultrasound of the carotid arteries, and a CT scan or MRI if it has not already been performed. Preventive anticoagulation (warfarin) is instituted if a source of clot within the cardiac chambers is found or if there is atrial fibrillation. Aspirin is appropriate but not imperative if no abnormality is found. Control of elevated blood pressure and addressing high cholesterol levels are ancillary steps. The mistake is to ignore the potential significance of a small stroke or TIA.

The Patient with Atrial Fibrillation In patients with this arrhythmia who are over age 65 and in those of any age with valvular disease, anticoagulation with warfarin is virtually mandated unless there is excessive risk due to falling or hematologic disease. Patients below approximately age 65 who are “lone fibrillators” (have no other cardiac or systemic disease) need not receive anticoagulation unless there has been a previous embolism. Whether younger patients who have additional vascular risk factors, such as diabetes or hypertension, benefit from anticoagulation is not known. If warfarin is to be discontinued for a necessary surgical procedure, it should be reinstated as soon as the surgeon deems it safe, since this is a time of increased stroke vulnerability. It has been the sense of many cardiologists that intermittent atrial fibrillation and fibrillation-flutter tachycardias also represent a risk of cerebral embolism, but there are no adequate studies to confirm this.

The Patient with a Recent Stroke That May Not Be Complete Here the basic problem is whether a thrombotic infarction (venous or arterial) will spread and involve more brain tissue; or if embolic, whether the ischemic tissue will become hemorrhagic or another embolus will occur; or if there is an arterial dissection, whether it will give rise to emboli. Therapies are controversial in most of these circumstances. In some centers it is the practice to try to prevent propagation of a thrombus by administering heparin (or low-molecular-weight heparin) followed by warfarin, as discussed earlier. Thrombolytic agents are an alternative if the stroke has occurred within the previous 2 or 3 h and is not too large. Except perhaps in cases of recent myocardial infarction, atrial fibrillation, or carotid disease, it is not imperative to begin heparin immediately while awaiting the effects of warfarin.

The Inevident or Misconstrued Syndromes of Cerebrovascular Disease Although hemiplegia is the classic type of stroke, cerebrovascular disease may manifest itself by signs that spare the motor pathways but have the same serious diagnostic and therapeutic implications. The following stroke syndromes tend to be overlooked.

Sometimes disregarded is a leaking aneurysm presenting as a sudden and intense generalized headache lasting hours or days and unlike any headache in the past. Examination may disclose no abnormality except for a slightly stiff neck and raised blood pressure. Failure to investigate such a case by imaging procedures and examination of the CSF may permit the occurrence of a later massive subarachnoid hemorrhage. Small cerebral hemorrhages, subdural hematomas, or brain tumors figure into the differential diagnosis, which is usually settled by a CT scan or MRI.

A second unobvious stroke is one caused by occlusion of the posterior cerebral artery, usually embolic. This may not be recognized unless the visual fields are routinely tested at the bedside. The patient himself may not be aware of the difficulty or will complain only of blurring of vision or the need for new glasses. Accompanying deficits are inability to name colors or recognize manipulable objects or faces, difficulty in reading, etc. MRI or CT scanning usually corroborates the clinical diagnosis, and therapy is directed against further embolism or extension of the thrombosis.

Another inappropriate or confounding stroke that may be mistaken for psychiatric disease is an attack of paraphasic speech from embolic occlusion of a branch of the left middle cerebral artery. The patient talks in nonsensical phrases, appears confused, and does not fully comprehend what is said to him. He may perform satisfactorily at a superficial level and offer socially appropriate greetings and gestures. Only scrutiny of language function and behavior will lead to the correct diagnosis. Infarction (or trauma) of the dominant or nondominant temporal lobe and rarely of the cau-
date may produce an agitated delirium with few focal findings. This may be mistaken for a toxic or withdrawal state.

Parietal infarctions on either side (usually nondominant hemisphere) are often missed because the patient is entirely unaware of the problem or the symptoms create only a subtle confusional state, drowsiness, or only subtle problems with calculation, dialing a phone, reaching accurately for objects, or loss of ability to write. Extinction of bilaterally presented visual or tactile stimuli gives a clue; marked asymmetry of the optokinetic nystagmus response is sometimes the only definite sign.

A cerebellar hemorrhage may at first be difficult to recognize as a stroke. An occipital headache and complaint of dizziness with vomiting may be interpreted as a labyrinthine disorder, gastroenteritis, or myocardial infarction. A slight ataxia of the limbs, inability to sit or stand, and mild gaze paresis may not have been properly tested or have been overlooked. Early intervention by surgery may be lifesaving; but once the syndrome has progressed to the point of coma with pupillary abnormalities with bilateral Babinski signs, surgery is most often useless.

Periventricular white matter changes (leukoaraiosis) correlate poorly with cerebrovascular disease and may be misinterpreted. We prefer to ignore them unless they are extensive and obscure a new lacunar stroke.

The Comatose Stroke Patient The most common causes of vascular coma are intracranial hemorrhage—usually deep in the hemisphere, less often in the cerebellum or brainstem, extensive subarachnoid hemorrhage, and basal artery occlusion. After several days, brain edema surrounding a large infarction in the territory of the middle cerebral artery or adjacent to a hemorrhage may compress the midbrain and produce the same effect. Certain remedial surgical measures are still available in these circumstances: drainage of blood from the ventricles, shunting of the ventricles in cases of secondary hydrocephalus due to obstruction of the third ventricle or aqueduct, evacuation of a cerebral hemorrhage in cases of recent decline into stupor and coma, and hemicraniectomy in the case of massive stroke edema. Also, thrombolytic therapy and anticoagulants are sometimes successful in reversing the progression of basilar artery thrombosis. These procedures are best carried out in centers with experience in cerebrovascular intensive care. If coma persists or is deep and sudden, only supportive treatment is possible.

Seizures Following Stroke With the exception of infarction due to cerebral venous occlusion, epileptic seizures following stroke are not a great problem. As mentioned earlier and in other chapters of the book, seizures are quite infrequent as the initial manifestation of an ischemic stroke, and when they do occur in this fashion, an embolus is usually the causative mechanism. In the data presented by Lamy and colleagues (who were studying stroke in young patients with patent foramen ovale), when seizures occurred not at the outset but within the first week after stroke, as they did in 2 to 4 percent of their cases, about half had another seizure, usually single, during the next several years. However, the same was true for those with a first seizure after 1 week. No satisfactory study has been conducted to determine if these patients benefit from anticonvulsant therapy to prevent the second or subsequent seizures. Following the practice of most other neurologists, we prescribe phenytoin or an equivalent drug only if there has been a seizure and continue it for about 18 months. If the EEG continues to show focal sharp waves or other epileptic activity at that time, we continue the drug; if not, we may discontinue the medication. It is also clear that prophylactic anticonvulsant treatment of all stroke patients is not necessary.

CHAPTER 35
CRANIOCEREBRAL TRAUMA

Among the vast array of neurologic diseases, cerebral trauma ranks high in order of frequency and gravity. In the United States, in persons under 45 years of age, trauma is the leading cause of death, and more than half of these deaths are due to head injuries. Each year, according to the American Trauma Society, an estimated 500,000 Americans are admitted to hospitals following cerebral trauma; of these, 75,000 to 90,000 die and even larger numbers, most of them young and otherwise healthy, are left permanently disabled.

The basic problem in craniocerebral trauma is at once both simple and complex: simple because there is usually no difficulty in determining causation—namely, a blow to the head—complex because of a number of delayed effects that may complicate the injury. As for the trauma itself, nothing medical can be done, for it is finished before the physician arrives on the scene. At most there can be an assessment of the full extent of the immediate cerebral injury, an evaluation of factors conducive to complications and further lesions, and the institution of measures to avoid such additional problems. But of the disastrous intracranial phenomena that can be initiated by head injury, several fall within the purview of the neurologist, for they are secondary effects that evolve during the period of medical observation, offering possibilities of treatment. No doubt, new techniques of cellular biology will expose phenomena that are set in motion by traumatic injury of nerve cells and glia. Some of these changes may be reversible, but at the moment, such knowledge is limited.

It is a common misconception that craniocerebral injuries are matters that concern only the neurosurgeon and not the general physician or neurologist. Actually, some 80 percent of head injuries are first seen by a general physician in an emergency department, and probably fewer than 20 percent ever require neurosurgical intervention of any kind—even this number is decreasing. Often the neurologist must take charge of the head-injured patient, or his opinion is sought in consultation. To enact his role effectively, he must be familiar with the clinical manifestations and the natural course of primary brain injury and its complications and have a sound grasp of the underlying physiologic mechanisms. Such knowledge must be up to date and immediately applicable, particularly as it relates to the interpretation of computed tomography (CT) and magnetic resonance imaging (MRI), both of which have greatly enhanced our ability to deal with head trauma and its complications. The present chapter reviews the salient facts concerning craniocerebral injuries and outlines a clinical approach that the authors have found useful over the years. Matters pertaining to spinal injury are considered in Chap. 44.

DEFINITIONS AND MECHANISMS

The very language that one uses to discuss certain types of head injury divulges a number of misconceptions inherited from previous generations of physicians. Certain words have crept into the medical vocabulary and have often been retained long after the ideas for which they stood have been refuted—attesting to the disadvantage of premature adoption of explanatory terms rather than descriptive ones. The word concussion, for example, implies a violent shaking or jarring of the brain and a resulting transient functional impairment. Yet despite numerous postulates of physical changes within nerve cells, axons, or myelin sheaths (vibration effects, formation of intracellular vacuoles, etc.), little convincing confirmation of their existence has been possible in humans or in experimental animals. Similarly the word contusion, meaning a bruising of cerebral tissue without interruption of its architecture, is applied rather indiscriminately to a variety of clinical states, some of which could not depend on a pathologic change of this type, e.g., “minor contusion state or syndrome”—an expression introduced by Wilfred Trotter, who was himself critical of words that “embalm a fallacious theory.”

In all attempts to analyze the mechanisms of closed, or blunt (nonpenetrating), head injury, one fact stands pre-eminent—that there must be the sudden application of a physical force of considerable magnitude to the head. Unless the head is struck, the brain suffers no injury—except in the rare instances of violent flexion-extension (whiplash) of the neck and somewhat controversial cases of crush injury to the chest or explosive injury with a sudden extreme increase of intrapulmonary pressure. The factors of particular importance in brain injury are the differential mobility of the head and brain, the tethering of the upper brainstem while allowing movement of the cerebral hemispheres, and the relationship of injured parts of the brain to dural septa and bony prominences. As to concussive injuries, it is useful to point out that all concussions involve a physical force that imparts motion to the stationary head or a hard surface that arrests the motion of a moving head, i.e., concussion does not occur if the head is stationary. This is the basis of most civilian head injuries, and they are notable in two respects: (1) they frequently induce at least a temporary loss of consciousness and (2) even though the skull is not penetrated, the brain may suffer gross damage, i.e., contusion, laceration, hemorrhage, and swelling. A theory that would bring into plausible form these physical and gross neuropathologic changes and their relation to transient loss of consciousness (concussion) or prolonged coma has been formulated only in relatively recent years.

By contrast, high-velocity missiles may penetrate the skull and cranial cavity or, rarely, the skull may be compressed between two converging forces that crush the brain without causing significant displacement of the head or the brain. In these circumstances the patient may suffer severe and even fatal injury without immediate loss of consciousness. Hemorrhage, destruction of brain tissue, and, if the patient survives for a time, meningitis or abscess are the principal pathologic changes created by injuries of these types. They offer little difficulty to our understanding. These various types of head injuries are illustrated in Fig. 35-1.

The relation of skull fracture to brain injury has been viewed in changing perspective throughout the history of this subject. In the first half of the century, fractures dominated the thinking of the medical profession, and cerebral lesions were regarded as secondary. Later, it became known that the skull, though rigid, is still flexible enough to yield to a blow that could injure the brain without causing fracture. Therefore the presence of a fracture, although a rough measure of the force to which the brain has been exposed, is no longer considered an infallible index of the presence of ce-
rebral injury. Even in fatal head injuries, autopsy reveals an intact skull in some 20 to 30 percent of cases (see also page 754). Contrariwise, many patients suffer skull fractures without serious or prolonged disorder of cerebral function, largely because the energy of a blow is dissipated in the fracture.

The modern trend is to be concerned primarily with the presence or absence of brain injury rather than with the fracture of the skull itself. Nevertheless, fractures cannot be dismissed without further comment for several reasons. The presence of a fracture always warns of the possibility of underlying cerebral injury. Overall, brain injury is estimated to be 5 to 10 times more frequent with skull fractures than without them and perhaps 20 times more frequent with severe and multiple fractures. Moreover, fractures assume importance by indicating the site and possible severity of brain damage, in providing an explanation for certain cranial nerve palsies, and in creating potential pathways for the ingress of bacteria and air or the egress of cerebrospinal fluid (CSF). In all these respects, fractures through the base of the skull are of special significance, more so than those of the cranial vault, and are considered below.

**Basal Skull Fractures and Cranial Nerve Injuries**

Some of the major sites and directions of basilar skull fractures are indicated in Fig. 35-2. One can readily perceive the possibilities of injury to cranial nerves in relation to such fractures. Fractures of the base are often difficult to detect in plain skull films, but their presence should always be suspected if any one of a number of characteristic clinical signs is in evidence. Fracture of the petrous pyramid often deforms the external auditory canal or tears the tympanic membrane, with resultant leakage of CSF (otorrhea); or, blood may collect behind an intact tympanic membrane and discolor it. If the fracture extends more posteriorly, damaging the sigmoid sinus, the tissue behind the ear and over the mastoid process becomes boggy and discolored (Battle sign). Basal fracture of the anterior skull may also cause blood to leak into the periorbital tissues, imparting a characteristic “raccoon” or “panda bear” appearance. The presence of any of these signs calls for CT scanning of the skull base using bone window settings to detect a fracture.

The existence of a basal fracture is commonly indicated by signs of cranial nerve damage. The olfactory, facial, and auditory nerves are the ones most liable to injury, but any one, including the twelfth, may be damaged. *Anosmia and an apparent loss of taste* (actually a loss of perception of aromatic flavors, since the elementary modalities of taste are unimpaired) are frequent sequelae of head injury, especially with falls on the back of the head. In the majority of cases the anosmia is permanent. If unilateral, it will not be noticed by the patient. The mechanism of these disturbances is thought to be a displacement of the brain and tearing of the olfactory nerve filaments in or near the cribriform plate, through which they course.

A fracture in or near the sella may tear the stalk of the pituitary gland, with resulting *diabetes insipidus*. Rarely such a fracture may cause bleeding from a pre-existing pituitary adenoma and produce the syndrome of pituitary apoplexy (page 577). A fracture of the sphenoid bone may lacerate the optic nerve, with blindness from the beginning. The pupil is unreactive to a direct light stimulus but still reacts to a light stimulus to the opposite eye (consensual reflex). The optic disc becomes pale, i.e., atrophic, after an interval of several weeks. Partial injuries of the optic nerve result in scotomas and a troublesome blurring of vision.

**Complete oculomotor nerve injury** is characterized by ptosis, a divergence of the globes with the affected eye resting in an abducted and slightly depressed position, loss of medial and most of the vertical movements of the eye with diplopia, and a fixed, dilated pupil, as described in Chap. 13. Diplopia that is worse on looking down, and compensatory tilting of the head suggest *trochlear nerve* injury. In a series of 60 patients with head injury, Lepore found that fourth nerve palsy was the commonest cause of diplopia, occurring unilaterally twice as often as bilaterally, followed in frequency by damage to one or both third nerves, then, least often, a unilateral or bilateral sixth nerve palsy. Five of his patients had palsies that reflected damage to more than one nerve, and seven had supranuclear disorders of convergence. The long subarachnoid course of the fourth nerve is usually given as the explanation for its frequent injury, but this mechanism has never been validated. These optic and ocular motor nerve disorders must be distinguished from those due to displacement of the globe as a result of direct injury to the orbit and the oculomotor muscles.

CHAPTER 35 CRANIOCEREBRAL TRAUMA

Injury to the **ophthalmic and maxillary divisions of the trigeminal nerve** may be the result of either a basal fracture across the middle cranial fossa or a direct extracranial injury to the branches of the nerves. Numbness and paresthesias of the skin supplied by the nerve(s) or a neuralgia can be troublesome sequelae of these injuries.

The **facial nerve** may be involved in one of two ways. In the first type of injury, associated with transverse fractures through the petrous bone, there is an immediate facial palsy, probably due to contusion or transection of the nerve. Surgical anastomosis has sometimes been successful in this circumstance. The second, more common type, is associated with longitudinal fractures of the petrous bone, the facial palsy then often being delayed for several days—a sequence that may be misinterpreted as progression of the intracranial traumatic lesion. This latter type is usually transitory, and its mechanism is not known.

Injury to the **eighth cranial nerve** due to petrous fractures results in a loss of hearing or in postural vertigo and nystagmus coming on immediately after the trauma. Deafness due to nerve injury must be distinguished from the high-tone hearing loss due to **cochlear injury** and from deafness caused by bleeding into the middle ear and disruption of the ossicular chain (conduction deafness). Also, vertigo must be distinguished from the very common symptom of posttraumatic giddiness discussed in a later section. A fracture through the hypoglossal canal causes weakness of one side of the tongue. It should be kept in mind that blows to the upper neck may also cause lower cranial nerve palsies, either by direct injury to their peripheral extensions or as a result of **carotid artery dissection**, either of its cervical or intracranial segment.

### Carotid-Cavernous Fistula

A basal fracture through the sphenoid bone may lacerate the internal carotid artery or one of its intracavernous branches where it lies in the cavernous sinus. Within hours or a day or two, a disfiguring pulsating exophthalmos develops as arterial blood enters the sinus and distends the superior and inferior ophthalmic veins that empty into the sinus. The orbit feels tight and painful, and the eye may become partially or completely immobile because of pressure on the ocular nerves traversing the sinus (Fig. 14-4). The sixth nerve is affected most often and the third and fourth nerves less frequently. Also, there may be a loss of vision due to ischemia of the optic nerve and retina; congestion of the retinal veins and glaucoma are additional factors in the visual failure. Some 5 to 10 percent of fistulas resolve spontaneously, but the remainder must be obliterated by interventional radiologic means (by a detachable balloon inserted into the carotid artery via a transfemoral catheter) or by a direct surgical repair of the fistula (see Stern).

Not all carotid-cavernous fistulas are traumatic. They may occasionally occur with rupture of an intracavernous saccular aneurysm or in Ehlers-Danlos disease, where the connective tissue is defective; or the cause may be unexplained.

### Pneumocephalus, Aerocele, and Rhinorrhea (Cerebrospinal Fluid Leak)

If the skin over a skull fracture is lacerated and the underlying meninges are torn, or if the fracture passes through the inner wall of a paranasal sinus, bacteria may enter the cranial cavity, with resulting meningitis or abscess formation. Also, CSF that leaks into the sinus present as a watery discharge from the nose (CSF rhinorrhea). The nasal discharge can be identified as CSF by testing it for glucose with diabetic test tape (mucus has no glucose) or by the presence of fluorescein or iodinated water-soluble dye that is injected into the lumbar subarachnoid space and then absorbed by pledgets placed in the nasal cavity. Most cases of acute CSF rhinorrhea heal by themselves. If the condition is persistent or is complicated by an episode of meningitis, repair of the torn dura mater is indicated. The prophylactic use of antibiotics to prevent meningitis from a nasal CSF leak is currently not favored, but many neurosurgeons continue this practice, particularly in children (see page 599).

A collection of air in the cranial cavity (aerocele) is a common occurrence following skull fracture or following an extended neurosurgical procedure. It is usually found (by CT scan) in the epidural or subdural space over the cerebral convexities or between the hemispheres and serves only to warn of a potential route for the entry of bacteria into the cranium. Small collections of air are usually absorbed without incident, but a large collection of air may act as a mass and cause clinical deterioration after injury (tension pneumocranium; Fig. 35-3). Inhalation of 100% oxygen has a salutary effect, but needle aspiration of the air is required if it is causing clinical signs (Fig. 35-3).
Mechanisms of Concussion

Much has been written about the mechanisms of concussion and coma in closed, or blunt, head injury. Certain facts concerning these conditions stand out: (1) Concussion, meaning a reversible traumatic paralysis of nervous function, is always immediate (not delayed even by seconds). (2) The effects of concussion on brain function may last for a variable time (seconds, minutes, hours, or longer). To set arbitrary limits on the duration of loss of consciousness—i.e., to consider a brief loss as indicative of concussion and a prolonged loss as indicative of concussion or other traumatic cerebral lesion, as proposed in some older medical writings—is illogical and unsound physiologically. As pointed out by Symonds, any such difference is quantitative, not qualitative. Admittedly, in the more prolonged states of coma, there is a greater chance of finding hemorrhage and contusion, which undoubtedly contribute to the persistence of coma and the likelihood of irreversible change. (3) The optimal condition for the production of concussion, demonstrated originally by Denny-Brown and Russell, is a sudden change in the momentum of the head; i.e., either movement is imparted to the stationary head by a blow or movement of the head is arrested by a hard, unyielding surface. These two types of blunt (nonpenetrating) head injury are called accelerative and de accelerative, respectively.

The mechanism of concussive “cerebral paralysis” has been interpreted in various ways throughout medical history in light of the state of scientific knowledge at a particular period of time. The favored hypotheses for the better part of a century were “vasoparalysis” (suggested by Fischer in 1870) or an arrest of circulation by an instantaneous rise in intracranial pressure (proposed by Strohmeyer in 1864 and popularized by Trotter in 1932). Jefferson, in his essay on the nature of concussion (1944), convincingly refuted these vascular hypotheses. Later, Shatsky and coworkers, by the use of high-speed cineangiography, showed displacement of vessels but no arrest of circulation immediately after impact.

Beginning with the work of Denny-Brown and Russell in 1941, the physical factors involved in head and brain injury have been subjected to careful analysis. These investigators demonstrated, in the monkey and cat, that concussion resulted when the freely moving head was struck by a heavy mass. If the head was prevented from moving at the moment of impact, the same degree of force invariably failed to produce concussion. More recently, the importance of head motion per se was verified by Gennarelli and colleagues, who were able to induce concussion in primates by rapid acceleration of the head without impact, a condition that rarely occurs in humans.

Holbourn, a Cambridge physicist, from a study of gelatin models under conditions simulating head trauma, deduced that when the head is struck, movement of the partly tethered but suspended brain always lags (due to inertia); but inevitably the brain moves also, and when it does it must rotate, for it occupies a round skull whose motions (because of attachment to the neck) usually describe an arc. Pudenz and Sheldon and later Ommaya and coworkers (1974) proved the correctness of this assumption by photographing the brain through a transparent (Lucite) calvarium at the moment of impact. The brain is thus subjected to shearing stresses set up by rotational forces mainly in the sagittal plane centered at its point of tethering in the high midbrain and subthalamus. The torque at the level of the upper reticular formation would explain the immediate loss of consciousness, as described below. Also, these rotational movements of the brain provide a reasonable explanation for the occurrence of surface injuries in certain places, i.e., where the swirling brain comes into contact with bony prominences on the inner surface of the skull (petrous and orbital ridges, sphenoid wings), and of injuries to the corpus callosum, which is flung against the falx.

These views on the site and mechanism of concussion have been supported by a number of additional physiologic observations. Foltz and Schmidt, in 1956, suggested that the reticular formation of the upper brainstem was the anatomic site of concussive injury. They showed that in the concussed monkey, lemniscal sensory transmission through the brainstem was unaltered, but its effect in activating the high reticular formation was blocked. They also demonstrated that the electrical activity of the medial reticular formation was depressed for a longer time and more severely than that of the cerebral cortex.

In 1956 and again in 1961, Strich described the neuropathologic findings in patients who died months after severe closed head injuries that had caused immediate and protracted coma. In all of her cases—in which there were no signs of skull fracture, raised intracranial pressure, or gross subarachnoid hemorrhage—she observed an uneven but diffuse degeneration of the cerebral white matter. In cases of shorter survival (up to 6 weeks), she observed ballooning and interruption of axis cylinders. These findings were subsequently confirmed by Nevin, by J. H. Adams and colleagues, and by Gennarelli and coworkers, the last of these groups working with monkeys. It is noteworthy that in most of these cases, and subsequent ones reported by Jellinger and Seitelberger, there were...
also lesions in the region of the reticular activating system and small hemorrhagic softening in the corpus callosum, superior cerebellar peduncles, and dorsolateral tegmentum of the midbrain. Strich interpreted the extensive white matter lesions, both in the hemispheres and in the brainstem, to represent a degeneration of nerve fibers that had been stretched or torn by the shear stresses set up during rotational acceleration of the head (diffuse axonal injury), as had been postulated earlier by Holbourn. She suggested that if nerve fibers are stretched rather than torn, the lesions may be reversible and may play a part in the mechanism of concussion. Symonds elaborated this view and saw in the shearing stresses—which are maximal at the point where the cerebral hemispheres rotate on the relatively fixed brainstem (i.e., at the midbrain-subthalamic level)—the explanation of concussion. The extension of this idea, namely that diffuse axonal injury throughout the cerebral white matter is the main cause of persistent unconsciousness, has been widely adopted but—as we discuss further on—is open to dispute. Indeed, even the proponents of diffuse axonal injury as an important effect of severe brain damage have found that thalamic lesions are almost always present in cases of prolonged coma or the persistent vegetative state (Adams et al 2000).

Clinical Manifestations of Concussion The immediate abolition of consciousness, suppression of reflexes (falling to the ground if standing), transient arrest of respiration, a brief period of bradycardia, and fall in blood pressure following a momentary rise at the time of impact are the characteristic clinical signs of concussive injury. Rarely, if these abnormalities are sufficiently intense, death may occur at the moment of impact, presumably from respiratory arrest. Usually the vital signs return to normal and stabilize within a few seconds while the patient remains unconscious. Brief tonic extension of the limbs, clonic convulsive movements lasting up to about 20 seconds and other peculiar movements may occur immediately after the loss of consciousness (see McCrory et al). These “coup lesions” are probably of little significance and have not been shown to confer an increased risk of future seizures. McCrory and colleagues noted an association between motor and convulsive movements and facial impact, and we have seen this feature twice in teenagers who collided while pursuing a ball. The plantar reflexes are transiently extensor. Then, after a variable period of time, the patient begins to stir and opens his eyes but is unseeing. Corneal, pharyngeal, and cutaneous reflexes, originally depressed, return, and the limbs are withdrawn from painful stimuli. Gradually contact is made with the environment, and the patient begins to obey simple commands and respond slowly and inadequately to simple questions. Memories are not formed during this period; the patient may even carry on a conversation which, later on, he cannot recall. Finally there is full recovery, corresponding to the time when the patient can form consecutive memories of current experiences.

The time required for the patient to pass through these stages of recovery may be only a few seconds or minutes, several hours, or possibly days; but again, between these extremes there are only quantitative differences, varying with the intensity of the process. To the observer, such patients are comatose only from the moment of injury until they open their eyes and begin to speak; however, for the patient, the period of unconsciousness extends from a point before the injury occurred (retrograde amnesia) until the time when he is able to form consecutive memories—at the end of the period of retrograde amnesia. The duration of the amnesic period, particularly of anterograde amnesia, is the most reliable index of the severity of the concussive injury. If there is no disturbance or loss of consciousness, none of the lesions described below are likely to be found. More recently, the notion has been introduced that momentary “stunning” represents the mildest degree of concussion. This state has found its way into various guidelines for the management of sports injuries, but there is no reason at the moment to presume it shares the same mechanism as concussion.

Pathologic Changes Associated with Severe Head Injury

In fatal cases of head injury, the brain is often bruised, swollen, and lacerated and there may be hemorrhages, either meningeal or intracerebral, and hypoxic-ischemic lesions. The prominence of these pathologic findings was responsible for the long-prevailing view that cerebral injuries are largely a matter of bruises (contusions), hemorrhages, and the need for urgent operations. That this can hardly be the case is indicated by the fact that some patients survive and make an excellent recovery from head injuries that are clinically as severe or almost as severe as the fatal ones. One can only conclude, therefore, that most of the immediate symptoms of severe head injury depend on histologically invisible and highly reversible functional changes, including those underlying concussion.

The effects of bruises, lacerations, hemorrhages, localized swellings, white matter necroses, and herniations of tissue should not be minimized, since they are probably responsible for or contribute to many of the fatalities that occur 12 to 72 h or more after the injury. As pointed out by Jennett, a majority of patients who remain in coma for more than 24 h after a head injury are found to have intracerebral hematomas. Of these lesions, the most important are contusions of the surface of the brain beneath the point of impact (coup lesion) and the more extensive lacerations and contusions on the side opposite the site of impact (contre-coup lesion), as shown in Fig. 35-4. Blows to the front of the head produce mainly coup lesions, whereas blows to the back of the head cause mainly contrecoup lesions. Blows to the side of the head produce either coup or contrecoup lesions or both. Irrespective of the site of the impact, the common sites of cerebral contusions are in the frontal and temporal lobes, as illustrated in Figs. 34-4 and 35-5. The inertia of the malleable brain—which causes it to be flung against the side of the skull that was struck, to be pulled away from the contralateral side, and to be impelled against bony prominences within the cranial cavity—explains these coup-contre-coup patterns. As noted, the experimental studies of Ommaya and others indicate that the effects of linear acceleration of the head are much less significant than are those due to rotation. Relative sparing of the occipital lobes in coup-contre-coup injury is explained by the smooth inner surface of the occipital bones and subjacent meninges as pointed out by Courville.

The contused cortex is diffusely swollen and hemorrhagic, most of the blood being found around parenchymal vessels. On CT scanning, the contusions appear as edematous regions of cortex and subcortical white matter admixed with areas of increased density representing leaked blood (Fig. 35-6). The bleeding points may coalesce and give the appearance of a clot in the cortex and immediately adjacent white matter. The predilection of these lesions for the crowns of convolutions attests to their traumatic origin (being thrown against the overlying skull) and distinguishes them from cerebrovascular and other types of cerebral lesions.

In nearly all cases of severe head injury there is damage to the corpus callosum by impact with the falx; necrosis and hemor-

Primary brainstem hemorrhages, are distinguished from the secondary hemorrhages resulting from the effects of downward displacement of the brainstem (transiential herniation). Duret originally emphasized the medullary location of these hemorrhages, but the term Duret hemorrhage has come to signify any secondary brainstem hemorrhage.

In addition to contusions and extradural, subdural, subarachnoid, and intracerebral hemorrhages, there are variable degrees of vasogenic edema that increases during the first 24 to 48 h, and zones of infarction due to vascular spasm caused by subarachnoid blood surrounding basal vessels. Marmarou et al have convincingly demonstrated that brain swelling after head injury is essentially the result of edema and not an increase in cerebral blood volume, as has long been postulated. In children and in some cases in adults, the cerebral edema may be massive and lead to secondary brainstem compression.
CHAPTER 35  CRANIOCEREBRAL TRAUMA

APPROACH TO THE PATIENT WITH HEAD INJURY

The physician first called on to attend a patient who has had a closed (blunt) head injury will generally find the patient in one of three clinical conditions, each of which must be dealt with differently. Usually it is possible to categorize the patient by assessing his mental and neurologic status when first seen and at intervals after the accident. In many emergency wards and intensive care units, the Glasgow Coma Scale is used as a rapid reference to accomplish this purpose (Table 35-1). It registers three aspects of neurologic function: eye opening, verbal response, and motor response to various stimuli. The scores provided by this scale have been found to correspond roughly with outcome of the head injury, as discussed further on. The scale uses a summed score with a maximum of 15; a score of 7 or less is considered to reflect severe trauma and a poor clinical state, 8 to 12, moderate injury, and higher scores, mild injury.

Patients Who Are Conscious or Are Rapidly Regaining Consciousness (Minor Head Injury)

This is the most frequently encountered clinical situation. Roughly, two degrees of disturbed function can be recognized within this category. In one, the patient was not unconscious at all but only stunned momentarily or “saw stars.” This injury is insignificant when judged in terms of life or death and brain damage—though, as we point out further on, there is always the possibility of a skull fracture or the later development of an epidural or subdural hematoma. Moreover, the patient is still liable to a troublesome post-

Figure 35-6. CT scan without contrast infusion showing areas of hemorrhagic contusion adjacent to bony prominences. There is also slight subarachnoid blood along the tentorium and in the insular cisterns, both typical of traumatic bleeding.

Figure 35-7. CT scan (left) and MRI (right) from a patient with diffuse axonal injury. There are multiple small hemorrhagic areas (one of which is shown by the dark arrow) in the cerebral white matter. The MRI highlights the small amount of blood in these lesions. Also shown are a contusion in the anterior temporal lobe (white arrow), which often accompanies the deep type of axonal injury, and blood in the ventricle.
Traumatic syndrome—consisting of headache, giddiness, fatigability, insomnia, and nervousness—which may appear soon after or within a few days of the injury. In the second instance, consciousness was temporarily abolished for a few seconds or minutes, i.e., the patient was genuinely concussed. When such a patient is first seen, recovery may already be complete, or he may be in one of the stages of partial recovery described earlier, under "Clinical Manifestations of Concussion." Even though mentally clear, the patient may have an amnesia for events immediately preceding and following the injury. Thereafter, headache and other symptoms of the posttraumatic syndrome or compensation neurosis may develop.

In most cases of this type, there is little need of a neurologic consultation, and hospitalization is not required provided that a responsible family member is available to report any change in the clinical state. In only a small group of these patients, mainly in those who are slow in regaining consciousness or have a skull fracture, is there significant risk of ongoing hemorrhage or other delayed complications.

Whether to obtain x-ray films of the head routinely in such patients is an unresolved problem. In our litigious society, the physician is inclined to do so. If there is no fracture and the patient is mentally clear, Jennett estimates that there is only one chance in a thousand of developing an intracranial (extradural) hemorrhage. He states that this increases to 1 in 30 in patients with a fracture; but most studies, such as the one by Lloyd and colleagues, have found that the presence of a skull fracture in children proves to be a relatively poor indicator of intracranial injury.

With a focus on cost-effective use of ancillary testing, there has also been considerable discussion of the criteria that justify obtaining a cranial CT following seemingly minor forms of head trauma. In our view, a CT should generally be obtained in a case of head injury associated with prolonged loss of consciousness, severe and persisting headache, nausea and vomiting, a confusional state, and any new, objective neurologic signs. The CT scan may be particularly important in elderly patients with minor head trauma, in whom the presence of an intracranial lesion (mainly subdural hematoma) may not be predicted by clinical signs. However, in children, it may be advisable to perform the scans more liberally. This is underscored by the results of a study of 215 children with minor head trauma conducted by Simon and colleagues; 34 children with no known loss of consciousness and a Glasgow Coma Scale score of 15 nonetheless displayed intracranial lesions, although only 3 required surgery.

These minor and seemingly trivial head injuries may sometimes be followed by a number of puzzling and worrisome clinical phenomena, some insignificant, others serious and indicative of a pathologic process other than concussion. The latter are described below. When they occur, a neurologic or neurosurgical evaluation is indicated.

Delayed Fainting after Head Injury Following an accident, the injured person, after walking about and seeming to be normal, may turn pale and fall unconscious to the ground. Recovery occurs within a few seconds or minutes. This is a vasodepressor syncope attack, possibly related to pain and emotional upset, and differs in no way from the fainting that follows pain and fright without injury. Such syncopal attacks also occur with injuries that spare the head, but with head injury they become more difficult to interpret.

Denny-Brown described a more severe type of delayed posttraumatic collapse that we have seen only rarely. Again, the patient appears to be recovering from a blow to the head, which may simply have dazed him or caused a brief period of unconsciousness; when suddenly, after a period of several minutes to hours, he collapses and becomes unresponsive for a brief time. The most disquieting feature of this clinical state is a marked bradycardia, which, coupled with the lucid interval, raises the specter of an evolving epidural hemorrhage (actually, bradycardia is a late and inconstant sign of epidural bleeding). However, intracranial pressure is not raised, the disorder fails to develop further, and—following a brief period of restlessness, vomiting, and headache—the patient recovers completely over a period of several days. Denny-Brown suggested that this form of delayed posttraumatic collapse was due to a contusion of the medulla, but how this explains the sequence of clinical events is not clear. The authors believe it possibly to be a severe form of vasodepressor syncope but have no firm explanation.

A more serious form of delayed collapse after head injury is described further on, under “Concussion Followed by a Lucid Interval.”

Drowsiness, Headache, and Confusion This syndrome occurs most often in children, who, after a concussive or nonconcussive head injury, seem not to be themselves. They lie down, are drowsy, complain of headache, and may vomit—symptoms that suggest the presence of an epidural or subdural hemorrhage. Mild focal edema near the point of impact may be seen on MRI. There is usually no skull fracture but, as Nee and colleagues point out, vomiting is associated with an increase in the incidence of skull fracture. The symptoms subside after a few hours, attesting to the benign nature of the condition.

Transient Traumatic Paraplegia, Blindness, and Migrainous Phenomena With falls or blows on top of the head, both legs may become temporarily weak and numb, with wavering bilateral Babinski signs and sometimes with sphincteric incontinence. Blows to the occiput may cause temporary blindness. The symptoms disappear after a few hours. It seems unlikely that these transient symptoms represent a direct localized concussive effect, caused either by indentation of the skull or by impact on these parts.

of the brain against the inner table of the skull. A concussion of the cervical portion of the spinal cord is another suggested but improbable mechanism of transient paraplegia. The blindness and paraplegia are usually followed by a throbbing vascular type of headache. Transient migrainous visual phenomena, aphasia, or hemiparesis, followed by a headache, are observed sometimes after minimal concussion in athletes who participate in competitive contact sports. Possibly all of these phenomena are due to an attack of migraine or migraine equivalent induced by a blow to the head. This can be perplexing for a few hours, especially if it is the first such attack of migraine in a child. Another clinical possibility, particularly in cases of acute quadriplegia, is cartilagenous embolism of the cervical cord (page 1072).

**Delayed Hemiplegia**  In our experience, most examples of these disorders have occurred in male adolescents or young adults who, some hours after a relatively minor athletic or more severe road injury, developed a massive hemiplegia, homonymous hemianopia, or aphasia (with left-sided lesions). Imaging or ultrasound may reveal a dissection of the internal carotid artery. The dissection may occur in the extracranial or the intracranial portion of the carotid artery and should be sought by MR angiography or arteriography if the hemiparesis has no other explanation. In other instances, particularly after a blow to the neck, a mural thrombus forms in the carotid, which, in turn, may shed an embolus to the anterior or middle cerebral artery. In yet other instances, the hemiplegia has no explanation other than the blow to the head, perhaps the result of the migraine phenomenon described above.

Other causes of delayed hemiplegia are a late evolving epidural or subdural hematoma and, in more severe injuries, an intracerebral hemorrhage (occasionally from a pre-existent arteriovenous malformation). Most of these are associated with a diminution in the level of consciousness.

**Fat Embolism**  With fractures of large bones, there may be, after 24 to 72 h, an acute onset of pulmonary symptoms (dyspnea and hyperpnea) followed by coma with or without focal signs or seizures; this sequence is due to systemic fat embolism, first of the lungs and then of the brain. In some cases the onset of pulmonary symptoms is associated with a petechial rash over the thorax, and one in three cases is said to show fat globules in the urine. Respiratory distress is the most important and often the only feature of the fat embolism syndrome, evident in the chest film as fluffy infiltrates in both lungs. In the brain, the fat emboli cause widespread petechial hemorrhages, involving both white and gray matter and a few larger infarcts. Most patients with fat embolism recover spontaneously in 3 or 4 days, although a mortality rate of up to 10 percent is quoted, usually related to the underlying injuries. Treatment, aside from respiratory support, is controversial. Heparin, which had been used in the past, is not considered effective.

**Patients Who Have Been Comatose from the Time of Head Injury**

Here the central problem, so ably set forth by Symonds, is the relationship between concussion and contusion. Since consciousness is abolished at the moment of injury, one can hardly doubt the existence of concussion in such cases; but when hours and days pass without consciousness being regained, the second half of the usual definition of concussion—namely, that the paralysis of cerebral function be transitory—is not satisfied. Careful pathologic examination of such cases usually discloses evidence of increased intracranial pressure and of cerebral contusions, lacerations, subarachnoid hemorrhage, zones of infarction, and scattered intracerebral hemorrhages—both at the point of injury (coup) and on the opposite side (contre coup), in the corpus callosum, and between these points, along the line of force of the injury. In some patients, the diffuse axonal type of injury is a prominent abnormality; most often, there are separate but strategically placed ischemic and hemorrhagic lesions in the upper midbrain and lower thalamic region, as already mentioned. The tissue around the contusions is swollen, and in postmortem preparations the white matter in these regions appears pale in myelin stains. Varying amounts of blood in the subdural space are usually present. A major displacement of the thalamus and midbrain is frequently present, with compression of the opposite cerebral peduncle against the free margin of the torus as well as secondary midbrain hematomas and zones of necrosis; in some cases, there is frank transtentorial herniation.

It should be kept in mind that severe head injury is associated with an immediate arrest of respiration and sometimes with bradyarrhythmia and cardiac arrest. The effects on the brain of these systemic changes may in themselves be sufficiently profound to cause coma. Also, head injury often complicates alcohol and drug ingestion, so that the possibility of a toxic or metabolic encephalopathy as the cause (or a contributing cause) of stupor must always be considered.

Within this category of severe head injury and protracted coma, three clinical subgroups can be recognized: one in which cerebral and other bodily injuries are severe and may be incompatible with survival; a second in which improvement sets in within a few days or a week or two, followed by variable degrees of recovery but leaving the patient with residual neurologic signs; and a third and relatively small group in which the patients remain permanently comatose, stuporous, or profoundly reduced in their cerebral capacities, i.e., in the so-called vegetative and minimally conscious states (see Chap. 17). Of course there are many degrees of injury that fall between these three arbitrary subgroups. In all of these patients, following the initial period of stabilization, the matters of interest are the clinical and radiologic assessments, with the purpose of uncovering a surgically remediable lesion—namely a subdural or epidural hematoma—or a treatable intraparenchymal hematoma. In most cases, the discovery of such a mass lesion mandates surgical removal. But unless it is the only lesion, the procedure often proves to be insufficient and coma is likely to persist because of the associated cerebral damage. The recognition and management of these hematomas are described further on.

The first subgroup comprises patients who are so severely injured that their lives are obviously endangered. When first seen, such a patient may be in shock (possibly from rupture of a visceral organ or injury of the cervical cord), with hypotension, hypoxia, hypothermia, a fast thready pulse, and pale, moist skin. If this state persists along with deep coma, widely dilated fixed pupils, absent eye movements and corneal and pharyngeal reflexes, flaccid limbs, stertorous and irregular respirations or respiratory failure, death usually follows in a short time. Once respiration ceases and the electroencephalogram (EEG) becomes isoelectric, the clinical state corresponds to brain death, as described on page 306. However, the diagnosis of brain death should not be made immediately after injury, in order to allow time to exclude the effects of anoxia, drug or alcohol intoxication, and hypotension. In some of these patients, the blood pressure and respirations stabilize; the degree of cerebral injury can then be evaluated over a period of hours by observing the depth of coma and the temperature, pulse, and blood pressure. Deep coma with subnormal temperature and rising pulse rate are grave prognostic signs, as are a rapidly rising temperature and pulse rate with rapid, irregular respirations. In some fatal cases, the tem-
perature continues to rise until the end, when there is circulatory collapse.

In this category of severe cerebral injury, where the patients survive for only a few hours or days, postmortem examination commonly discloses cerebral contusion and focal hemorrhage, necrosis of tissue, and brain swelling. In the Traumatic Coma Data Bank, which included 1030 gravely injured patients with Glasgow Coma Scale scores of 8 or less, 21 percent had subdural hematomas, 11 percent had intracerebral clots, and 5 percent had epidural hematomas. Notable, however, is the fact that half the patients had no mass lesions on the CT scan. On the basis of CT criteria, these patients were thought to have diffuse axonal injury. However, in 50 consecutive autopsies of severely injured patients, summarized in an earlier era by Rowbotham, all but two showed macroscopic changes, indicating the relative unreliability of CT analysis. The lesions in these cases consisted of surface contusions (48 percent), lacerations of the cerebral cortex (28 percent), subarachnoid hemorrhage (72 percent), subdural hematoma (15 percent), extradural hemorrhage (20 percent), and skull fractures (72 percent). As these figures indicate, several of these changes were found in the same patient. Moreover, trauma of extracranial organs and tissues is frequent and obviously contributes to the fatal outcome.

Among patients who survived and remained vegetative until death, Adams and colleagues (2000) found that 80 percent had thalamic damage and 71 percent had findings of diffuse axonal injury, as discussed earlier. This leaves in somewhat ambiguous status the proximate cause of the persistent vegetative state after blunt head injury, but it does emphasize the frequency of bilateral thalamic damage in cases of the vegetative state from all causes.

In respect to the second subgroup, i.e., the relatively less severe and seldom fatal head injuries, all gradations in tempo and degree of recovery can be observed. In the least severely injured of this group, recovery of consciousness begins in a few hours, although there may be a relapse within the first day or two as a result of swelling of the contused brain tissue, enlargement of a subdural hematoma, brain hemorrhage, or infarction, the last provoked by arterial spasm in relation to subarachnoid hemorrhage. The CSF is usually bloody. Eventually, recovery may be nearly complete, but the period of traumatic amnesia covers a span of several days or even weeks.

In this second subgroup, the sequence of clinical events is the same as that described in relation to concussion except that their duration is more protracted. Stupor gives way to a confusional state that may last for weeks, and it may for a variable period be associated with aggressive behavior and uncooperativeness (traumatic delirium). The period of traumatic amnesia is proportionately longer than in the less severely injured. It is during the period of recovery of consciousness that focal neurologic signs (hemiparesis, aphasia, abulia, etc.) become more obvious, though some unilateral signs may have been detected during the comatose period. Once the patient improves to the point of being able to converse, he is demonstrably slow in thinking, with few mental associations; unstable in emotional reactions; and faulty in judgment—a state sometimes referred to as “traumatic dementia.”

Finally there is that relatively small, distressing group of severely brain-injured patients in whom the vital signs become normal but who never regain full consciousness. As the weeks pass, the prospects become more bleak. Such a patient, especially if a child, may still emerge from coma after 6 to 12 weeks and make a surprisingly good though usually incomplete recovery, but such instances are decidedly rare. Some of those who survive for long periods open their eyes and move their heads and eyes from side to side but betray no evidence of seeing or recognizing even the closest members of their families. They do not speak and are capable of only primitive postural or reflex withdrawal movements. Jennett and Plum referred to this as the “persistent vegetative state” (see page 305). Fourteen percent of the patients in the Traumatic Coma Data Bank remained in this state. Hemiplegia or quadriplegia with varying degrees of decerebrate or decorticate posturing is usually demonstrable. Life is mercifully terminated after several months or years by some medical complication. Our colleague R. D. Adams has examined the brains of 14 patients who remained in coma and in vegetative states from one to 14 years. All showed extensive zones of necrosis and hemorrhage in the upper brainstem.

In generalizing about this category of head injury, i.e., patients who are and have been comatose from the time of injury, the effects of contusion, hemorrhage, and brain swelling often become evident within 18 to 36 h after the injury and then may progress for several days. If the patients survive this period, their chances of dying from complications of these effects—such as increased intracranial pressure, herniations of the temporal lobe, subdural hemorrhage, hypoxia, and pneumonia—are greatly reduced. The mortality rate of those who reach the hospital in coma is about 20 percent, and most of the deaths occur in the first 12 to 24 h as a result of direct injury to the brain in combination with other nonneurologic injuries. Of those alive at 24 h, the overall mortality falls to 7 to 8 percent; after 48 h, only 1 to 2 percent succumb. There is some evidence that transfer of such patients to an intensive care unit, where they can be monitored by personnel experienced in the handling of head injury, improves the chances for survival (see further on).

**Concussion Followed by a Lucid Interval and Serious Cerebral Damage**

This group is smaller than the other two but is of great importance because it includes a disproportionate number of patients who are in urgent need of surgical treatment. The initial coma may have lasted only a few minutes or, exceptionally, there may have been none at all—in which instance one might wrongly conclude that since there was no concussion, there is no possibility of traumatic hemorrhage or other type of brain injury. Patients who display this sequence of events, referred to as “talk and die” by Marshall and associates, deteriorate because of the delayed expansion of a small subdural hematoma, worsening brain edema, or occasionally the late appearance of an epidural clot. Among 34 such patients in the Traumatic Coma Data Bank, the majority showed substantial degrees of midline shift on the initial CT scan, reflecting the presence of early brain edema and contusion (Marshall et al). A similar condition of delayed intracerebral hematoma, discussed further on (Spänapoplexie), is a feature of a more severe initial head injury that engenders coma from the onset.

**SPECIFIC TRAUMATIC CRANIAL LESIONS** (Table 35-2)

The following conditions must be considered in all cases of these delayed types but occur as often with serious initial injury.

**Acute Epidural Hemorrhage**

As a rule, this arises with a temporal or parietal fracture and laceration of the middle meningeal artery or vein. Less often, there is a tear in a dural venous sinus. The injury, even when it fractures the skull, may not have produced coma initially, or it may be part
of a devastating craniocerebral injury. A typical example is that of a child who has fallen from a bicycle or swing or has suffered some other hard blow to the head and was unconscious only momentarily. A few hours or a day later (exceptionally, with venous bleeding the interval may be several days or a week), headache of increasing severity develops, with vomiting, drowsiness, confusion, aphasia, seizures (which may be one-sided), hemiparesis with slightly increased tendon reflexes, and a Babinski sign. As coma develops, the hemiparesis may give way to bilateral spasticity of the limbs and Babinski signs. The pulse is often slow (below 60 beats per minute) and bounding, with a concomitant rise in systolic blood pressure (Cushing effect). The pupil may dilate on the side of the hematoma. Physicians need not be reminded that lumbar puncture is contraindicated in this setting, particularly now that CT and MRI are available. Death, which is almost invariable if the clot is not removed surgically, comes at the end of a comatose period and is due to respiratory arrest. The visualization of a fracture line across the groove of the middle meningeal artery and knowledge of which side of the head was struck (the clot is usually on that side) are of aid in diagnosis and lateralization of the lesion. However, meningeal vessels may occasionally be torn without fracture. The CT scan reveals a lens-shaped clot with a smooth inner margin (Fig. 35-8). The surgical procedure consists of placement of burr holes in an emergency situation or, preferably, a craniotomy, drainage of the hematoma, and identification and ligation of the bleeding vessel. The operative results are excellent except in cases with extended fractures and laceration of the dural venous sinuses, in which the epidural hematoma may be bilateral rather than unilateral. If coma, bilateral Babinski signs, spasticity, or decerebrate rigidity supervene before operation, it usually means that displacement of central structures and crushing of the midbrain have already occurred; prognosis is then poor. Small epidural hemorrhages, followed by serial CT scanning, will be seen to enlarge gradually for a week or two and then be absorbed. There is always controversy about removing these in a patient who has no symp-

Acute and Chronic Subdural Hematomas

The problems created by acute and chronic subdural hematomas are so different that they must be discussed separately. In acute subdural hematoma, which may be unilateral or bilateral, there may be a brief lucid interval between the blow to the head and the advent of coma. Or, more often, the patient is comatose from the time of the injury and the coma deepens progressively. Frequently the acute subdural hematoma is combined with epidural hemorrhage, cerebral contusion, or laceration. The clinical effects of these several lesions are difficult to distinguish; there are some patients in whom it is impossible to state before operation whether the clot is epidural or subdural in location. Subdural clots more than 5 mm thick can be accurately visualized by the CT scan in more than 90 percent of cases (Fig. 35-9). A large acute clot causes a pineal shift as well as marked compression of one lateral ventricle; but if the clots are bilateral, there may be no shift and the ventricles appear symmetrical.

Acute, rapidly evolving subdural hematomas are due to tearing of bridging veins, and symptoms are caused by compression of the brain by an expanding clot of fresh blood. Unlike epidural arterial hemorrhage, which is steadily progressive, venous bleeding is usually arrested by the rising intracranial pressure.

Exceptionally, the subdural hematoma forms in the posterior fossa and gives rise to headache, vomiting, pupillary inequality, dysphagia, cranial nerve palsies, and, rarely, stiff neck and ataxia of the trunk and gait if the patient is well enough to be tested for these functions. Because of their apposition to bone or their axial orientation along the tentorial dura, posterior fossa clots are more likely than clots over the cerebral convexities to be missed in CT scans.

In chronic subdural hematoma, the traumatic etiology is often
less clear. The head injury, especially in elderly persons and in those taking anticoagulant drugs, may have been trivial and may even have been forgotten. A period of weeks then follows when headaches (not invariable), light-headedness, slowness in thinking, apathy and drowsiness, unsteady gait, and occasionally a seizure or two are the main symptoms. The initial impression may be that the patient has a vascular lesion or brain tumor or is suffering from drug intoxication, a depressive illness, or Alzheimer disease. A gradual expansion of the hematoma is believed to cause the progression of symptoms. As with acute subdural hematoma, the disturbances of mentation and consciousness (drowsiness, inattentiveness, incoherence of thinking, and confusion) are more prominent than focal or lateralizing signs, and they may fluctuate. The focal signs usually consist of hemiparesis and rarely of an aphasic disturbance. Homonymous hemianopia is seldom observed, probably because the geniculocalcarine pathway is deep and not easily compressed; similarly, hemiplegia, i.e., complete paralysis of one arm and leg, is usually indicative of a lesion within the cerebral hemisphere rather than a compressive lesion on its surface. An important feature of the hemiparesis from subdural hematoma, when it occurs, is that it may sometimes be ipsilateral to the clot, as a result of compression of the contralateral cerebral peduncle against the free edge of the tentorium by horizontal displacement of the midbrain (Kernohan-Woltman false localizing sign; see page 310). If the condition progresses, the patient becomes stuporous or comatose, but this course is often interrupted by striking fluctuations of awareness.

With both large acute and chronic hematomas, dilatation of the ipsilateral pupil is a fairly reliable indicator of the side of the hematoma, though this sign may be misleading (occurring on the opposite side in 10 percent of cases, according to Pevehouse and co-workers). Convulsions are seen occasionally, most often in alcoholics or in patients with cerebral contusions, but they cannot be regarded as a cardinal sign of subdural hematoma. Rare cases of internuclear ophthalmoplegia and of chorea have been reported but have not occurred in our material. Presumably they are a result of distortion of deep structures. Also, transient disturbances of neurologic function simulating transient ischemic attacks (TIAs) may occur. In infants and children, enlargement of the head, vomiting, and convulsions are prominent manifestations of subdural hematoma.

CT scanning with contrast infusion and MRI are the most reliable diagnostic procedures. On CT scans, the acute clot is initially hyperdense but becomes isodense after a period of time (Fig. 35-10), during which it may be difficult to detect except by the tissue shifts it causes. It then becomes progressively hypodense (with respect to the cortex) over 2 to 6 weeks. The evolution of signal changes in the MRI is similar to the sequential imaging changes found with parenchymal hematomas. The acute clot is hypointense on T2-weighted images, reflecting the presence of deoxyhemoglobin. Over the subsequent weeks, all image sequences show it as hyperintense as a result of methemoglobin formation. Eventually the chronic clot again becomes hypointense on the T1-weighted images. With contrast infusion, both imaging procedures usually reveal the vascular and reactive border surrounding the clot. Usually, by the fourth week, sometimes later, the hematoma becomes hypodense, typical of a chronic subdural hygroma.

Other formerly used investigative measures are seldom necessary but are mentioned here for completeness and in the event that the diagnosis is made in the course of evaluating some other neurologic problem. Skull films are helpful when there is calcification surrounding a chronic hematoma, a calcified pineal that is shifted to one side, or an unexpected fracture line is found. The EEG is usually abnormal bilaterally, sometimes with reduced voltage over the hematoma and high-voltage slow waves over the opposite side. In an arteriogram, the cortical branches of the middle cerebral artery are separated from the inner surface of the skull, and the anterior cerebral artery may be displaced contralaterally. The CSF may be clear and acellular but more often is bloody or xanthochromic depending on the presence or absence of recent or old contusions and subarachnoid hemorrhage; the pressure may be elevated or normal. A xanthochromic fluid with relatively low protein content should always raise the suspicion of chronic subdural hematoma.

The chronic subdural hematoma becomes gradually encysted by fibrous membranes (pseudomembranes) that grow from the dura. Some hematomas—probably those in which the initial bleeding was slight (see below)—resorb spontaneously. Others expand slowly and act as space-occupying masses (Fig. 35-11). Gardner, in 1932, first postulated that the gradual enlargement of the hematoma was due to the accession of fluid, particularly CSF, which was drawn into the hemorrhagic cyst by its increasing osmotic tension as red blood cells (RBCs) hemolyzed and protein was liberated. This hypothesis, which came to be widely accepted, is not supported by the available data. Rabe and colleagues demonstrated that the breakdown of RBCs contributes little if at all to the accumulation of fluid in the subdural space. According to the latter authors, the most important factor in the accumulation of subdural fluid is a pathologic permeability of the developing capillaries in the outer pseudomembrane of the hematoma. The CSF plays no discernible role in this process, contrary to the original view of Munro and Merritt. In any event, as the hematoma enlarges, the compressive effects increase gradually. Severe cerebral compression and displacement with temporal lobe–tentorial herniation are the usual causes of death.
hemisphere to expand after removal of a large clot. The difficulty of managing these patients surgically should not be underestimated. Elderly patients may be slow to recover after removal of the chronic hematoma or may have a prolonged period of confusion. Postoperative expansion of the brain can be followed by serial CT scans and may take weeks. Small, asymptomatic chronic collections are usually left alone and followed serially by clinical and CT examination, first at weekly and then monthly and yearly intervals.

Although no longer a common practice, the administration of corticosteroids is an alternative to surgical removal of subacute and chronic subdural hematomas in patients with minor symptoms or with some contraindication to surgery. Headache and other symptoms, such as gait difficulty or limb clumsiness, may resolve satisfactorily after several weeks of medication and may remain abated when the steroids are slowly reduced.

**Subdural Hygroma**

This encapsulated collection of clear or xanthochromic fluid in the subdural space may form after an injury as well as after meningitis (in an infant or young child). More often subdural hygromas appear without infection, presumably due to a ball-valve effect of an arachnoidal tear that allows cerebrospinal fluid to collect in the space between the arachnoid and the dura; brain atrophy is conducive to this process. Occasionally a hygroma originates from a tear in an arachnoidal cyst. It may be difficult to differentiate a long-standing subdural hematoma from hygroma, and some chronic subdural hematomas are probably the result of repeated small hemorrhages that arise from the membranes of hygromas. Shrinkage of the hypocerephal brain after ventriculoperitoneal shunting is also conducive to the formation of a subdural hematoma or hygroma, in which case drowsiness, confusion, irritability, and low-grade fever are relieved when the subdural fluid is aspirated or drained. In adults, hygromas are usually asymptomatic and do not require treatment.

**Cerebral Contusion**

Severe closed head injury is almost universally accompanied by cortical contusions and surrounding edema. The mass effect of contusional swelling, if sufficiently large, is a major factor in the genesis of tissue shifts and raised intracranial pressure. The CT appearance of contusion has already been described (page 751; see also Figs. 35-4 and 35-5). In the first few hours after injury, the bleeding points in the contused area may appear small and innocuous. The main concern, however, is the tendency for a contused area to swell or to develop into a hematoma. This may give rise to clinical deterioration hours to days after the injury, sometimes abrupt in onset and concurrent with the appearance of swelling of the damaged region on the CT scan. It has been claimed, on uncertain grounds, that the swelling in the region of an acute contusion is precipitated by excessive administration of intravenous fluids (fluid management is considered further on in this chapter). Craniotomy and decompression of the swollen brain is usually of little benefit.

**Traumatic Intracerebral Hemorrhage**

One or several intracerebral hemorrhages may be apparent immediately after head injury, or hemorrhage may be infrequently delayed in its development by several days (Spätapoplexie). The bleeding is in the subcortical white matter of one lobe of the brain.
or in deeper structures, such as the basal ganglia or thalamus. The injury is nearly always severe; blood vessels as well as cortical tissue are torn.

The clinical picture of traumatic intracerebral hemorrhage is similar to that of hypertensive brain hemorrhage (deepening coma with hemiplegia, a dilating pupil, bilateral Babinski signs, stertorous and irregular respirations). It may be manifest by an abrupt rise in blood pressure and in intracranial pressure. In elderly patients, it is sometimes difficult to determine whether a fall had been the cause or the result of an intracerebral hemorrhage. Craniotomy with evacuation of the clot has given a successful result in a few cases, but the advisability of surgery is governed by several factors, including the level of consciousness, the time from the initial injury, and the associated damage (contusions, subdural and epidural bleeding) shown by imaging studies. The wider application of intracranial pressure monitoring and of CT scans at intervals after the injury should facilitate diagnosis and perhaps help to elucidate the pathogenesis of delayed hemorrhages. Boto and colleagues determined that basal ganglia hemorrhages were prone to enlarge in the day or two after closed head injury and that those over 25 mL in volume were fatal in 9 of 10 cases.

It should be mentioned again that subarachnoid blood of some degree is very common after serious head injury. A problem that sometimes arises in cases that display both contusions and substantial subarachnoid blood is the possibility that a ruptured aneurysm was the initial event and that a resultant fall caused the contusions. In cases where the subarachnoid blood is concentrated around one of the major vessels of the circle of Willis, an angiogram may be justified to exclude the latter possibility. This subject is addressed in Chap. 34.

Acute Brain Swelling in Children

This condition is seen in the first hours after injury and may prove rapidly fatal. The CT scan shows enlargement of both hemispheres and compression of the basal cisterns and ventricles. There is usually no papilledema in the early stages, during which the child hyperventilates, vomits, and shows extensor posturing. The assumption has been that this represents a loss of regulation of cerebral blood flow and a massive increase in the blood volume of the brain. The administration of excessive water in intravenous fluids may contribute to the problem and should be avoided. Inappropriate secretion of antidiuretic hormone (ADH) also exaggerates the swelling in some children. We have not observed this complication in adults.

“Shaken Baby” Syndrome

This form of cranioencephal trauma in infants is well known in large emergency practices but can be missed if not specifically considered. As the name implies, the inciting trauma is typically violent shaking of the body or head of an infant, resulting in rapid acceleration and deceleration of the cranium combined with cervical whiplash. The presence of this type of injury must often be inferred from the combination of lesions on imaging studies or autopsy examination, but precision in examination is paramount because of its forensic and legal implications. The diagnosis is suspected from the combination of subdural hematomas and retinal hemorrhages, as summarized by Bonnier and colleagues. Sometimes there are occult skull fractures, but more often, there is little or no direct cranial trauma. Additional lesions may be evident on diffusion-weighted MRI, particularly in the white matter of the corpus callosum and the temporo-occipito-parietal region. This syndrome confers a high risk for slowing of development; there may be acquired microcephaly reflecting brain atrophy consequent to both contusions and infarctions. A low initial Glasgow Coma Scale score, severe retinal hemorrhages, and skull fractures are associated with poor outcomes. Old and recent fractures in other parts of the body should arouse suspicion of this syndrome.

Penetrating Wounds of the Head

Missiles and Fragments The descriptions in the preceding pages apply to blunt, nonpenetrating injuries of the skull and their effects on the brain. The disorders included in this section are more the concern of the neurosurgeon than the neurologist. In the past, the care of penetrating cranioencephal injuries was mainly the preoccupation of the military surgeon, but—with the increasing amount of violent crime in society—such cases have become commonplace on the emergency wards of general hospitals.

In civilian life, missile injuries are essentially caused by bullets fired from rifles or handguns at high velocities. Air is compressed in front of the bullet so that it has an explosive effect on entering tissue and causes damage for a considerable distance around the missile track. Missile fragments, or shrapnel, are pieces of exploding shells, grenades, or bombs and are the usual causes of penetrating cranial injuries in wartime. The cranial wounds that result from missiles and shrapnel have been classified by Purvis as tangential, with scalp lacerations, depressed skull fractures, and meningeal and cerebral lacerations; penetrating, with in-driven metal particles, hair, skin, and bone fragments; and through-and-through wounds. In most penetrating injuries from high-velocity missiles, the object (such as a bullet) causes a high-temperature coagulative lesion that is sterile and fortunately does not require surgery. In these instances, the main considerations are the development of infection or CSF leaks or, in the long term, epilepsy or aneurysms in distal blood vessels. The latter are considered to be the result of disruption of the vessel wall by the high-energy shock wave.

If the brain is penetrated at the lower levels of the brainstem, death is instantaneous because of respiratory and cardiac arrest. Even through-and-through wounds at higher levels, as a result of energy dissipated in the brain tissue, may damage vital centers sufficiently to cause death immediately or within a few minutes in 80 percent of cases. If vital centers are untouched, the immediate problem is intracranial bleeding and rising intracranial pressure from swelling of the traumatized brain tissue.

Once the initial complications are dealt with, the surgical problems, as outlined by Meirowsky, are reduced to three: prevention of infection by rapid and radical (definitive) debridement, accompanied by the administration of broad-spectrum antibiotics; control of increased intracranial pressure and shift of midline structures by removal of clots of blood and the vigorous administration of mannitol or other dehydrating agents as well as dexamethasone; and the prevention of life-threatening systemic complications.

When first seen, the majority of patients with penetrating cerebral lesions are comatose. A small metal fragment may have penetrated the skull without causing concussion, but this is not true of high-velocity missiles. In a series of 132 patients of the latter type analyzed by Frazier and Ingham, consciousness was lost in 120. The depth and duration of coma seemed to depend on the degree of cerebral necrosis, edema, and hemorrhage. In the series of the
Crushing Injuries of the Skull

Traumatic Coma Data Bank, the mortality rate in 163 patients who were initially comatose from a cranial gunshot wound was 88 percent—more than twice the mortality that results from severe blunt head injury. On emerging from coma, the patient passes through states of stupor, confusion, and amnesia, not unlike those following severe closed head injuries. Headache, vomiting, vertigo, pallor, sweating, slowness of pulse, and elevation of blood pressure are other common findings. Focal or focal and generalized seizures occur in the early phase of the injury in some 15 to 20 percent of cases.

Recovery may take many months. Frazier and Ingham comment on the “loss of memory, slow cerebration, indifference, mild depression, inability to concentrate, sense of fatigue, irritability, vasomotor and cardiac instability, frequent seizures, headaches and giddiness, all reminiscent of the residual symptoms from severe closed head injury with contusions.” Every possible combination of focal cerebral symptoms may be caused by such lesions. The classic articles by Feiring and Davidoff and also by Russell and by Teuber, listed at the end of this chapter, are still very useful references on this subject.

Epilepsy is the most troublesome sequela and is described below. Ascroft and also Caveness, in reviewing World War II cases, found that approximately half of all patients with wounds that had penetrated the dura eventually developed epilepsy, most often focal in nature; the figures reported by Caveness for Korean War veterans are about the same.

CSF rhinorrhea, discussed earlier and in Chap. 38, may occur as an acute manifestation of a penetrating injury that produces a fracture through the frontal, ethmoid, or sphenoid bones. Cairns listed these acute cases as a separate group in his classification of CSF rhinorrheas, the others being (1) a delayed form after cranio-cerebral injury, (2) a form that follows sinus and cranial surgery, and (3) a spontaneous variety. Pneumoencephalocele (aerocele)—i.e., air entering the cerebral subarachnoid space or ventricles spontaneously or as a result of sneezing or blowing the nose—is evidence of an opening from the paranasal sinus through the dura, as mentioned earlier in relation to skull fracture (Fig. 35-3).

Crushing Injuries of the Skull Aside from the absence of concussion, these relatively rare cerebral lesions present no special clinical features or neurologic problems not already discussed.

Birth Injuries These involve a unique combination of physical forces and circulatory-oxygenation factors and are discussed separately in Chap. 38.

SEQUELAE OF HEAD INJURY

Posttraumatic Epilepsy Epilepsy is the most common delayed sequela of cranio-cerebral trauma, with an overall incidence of about 5 percent in patients with closed head injuries and 50 percent in those who had sustained a compound skull fracture and wound of the brain. The basis is nearly always a contusion or laceration of the cortex. As one might expect, the risk of developing posttraumatic epilepsy is also related to the overall severity of the closed head injury. In a civilian cohort of 2747 head-injured patients described by Annegers and colleagues, the risk of seizures after severe head injury (loss of consciousness or amnesia for more than 24 h, including subdural hematoma and brain contusion) was 7 percent within 1 year and 11.5 percent in 5 years. If the injury was only moderate (unconsciousness or amnesia for 30 min to 24 h or causing only a skull fracture), the risk fell to 0.7 and 1.6 percent, respectively. After mild injury (loss of consciousness or amnesia of less than 30 min), the incidence of seizures was not significantly greater than in the general population. In a subsequent study (1998), Annegers et al expanded the original cohort to include 4541 children and adults with cerebral trauma. The results were much the same as those of the first study except that in patients with mild closed head injuries, there was only a slight excess risk of developing seizures—a risk that remained elevated only until the fifth year after injury. The likelihood of epilepsy is said to be greater in parietal and posterior frontal lesions, but it may arise from lesions in any area of the cerebral cortex. Also, the frequency of seizures is considerably higher after penetrating cranial injury, as cited above.

The interval between the head injury and the first seizure varies greatly. A small number of patients have a generalized seizure within moments of the injury (immediate epilepsy). Usually this amounts to a brief tonic extension of the limbs, with slight shaking movements immediately after concussion, followed by awakening in a mild confusional state. Whether this represents a true epileptic phenomenon or, as appears more likely, is the result of arrest of cerebral blood flow or a transient brainstem dysfunction is unclear. Some 4 to 5 percent of hospitalized head-injured individuals are said to have one or more seizures within the first week of their injury (early epilepsy). The immediate seizures have a good prognosis and we tend not to treat them as if they represented epilepsy; on the other hand, late seizures are significantly more frequent in patients who had experienced epilepsy in the first week after injury (not including the convulsions of the immediate injury) (Jennett).

In medical writings, the term posttraumatic epilepsy usually refers to late epilepsy, i.e., to seizures that develop several weeks or months after the head injury (1 to 3 months in most cases). Approximately 6 months after injury, half the patients who will develop epilepsy have had their first episode; by the end of 2 years, the figure rises to 80 percent (Walker). The interval between head injury and development of seizures is said to be longer in children. The longer the interval, the less certain one is of its relation to the traumatic incident. Data derived from a 15-year study of military personnel with severe (penetrating) brain wounds indicate that patients who escape seizures for 1 year after injury can be 75 percent certain of remaining seizure-free; patients without seizures for 2 years can be 90 percent certain; and for 3 years, 95 percent certain. For the less severely injured (mainly closed head injuries), the corresponding times are 2 to 6 months, 12 to 17 months, and 21 to 25 months (Weiss et al). Despite this, there is no doubt that seizures in adulthood occur for which there is no other explanation than a scarred cortical contusion that had been acquired decades before.

Posttraumatic seizures (both focal and generalized) tend to decrease in frequency as the years pass, and a significant number of patients (10 to 30 percent, according to Caveness) eventually stop having them. Status epilepticus is uncommon. Individuals who have early attacks (within a week of injury) are more likely to have a complete remission of their seizures than those whose attacks begin a year or so after injury. A low frequency of attacks is another favorable prognostic sign. Alcoholism has an adverse effect on this seizure state. Our colleagues have observed some 25 patients with posttraumatic epilepsy in whom seizures had ceased altogether for several years, only to recur in relation to drinking. In these patients the seizures were precipitated by a weekend or even one evening of heavy drinking and occurred, as a rule, not when the patient was intoxicated but in the “sobering-up,” or withdrawal, period.
The nature of the epileptogenic lesion has been elusive aside from the presence of a cortical scar. From the examination of old cortical contusions (plaques jaunes), one cannot, on morphologic grounds, determine whether a lesion had or had not been epileptogenic. Electroencephalograms of the brain in regions adjacent to old traumatic foci reveal a number of spontaneously electrically active zones adjacent to the scars. Microscopically, these foci show neuronal loss and an increase of astrocytes. It is postulated that abnormalities of dendritic branching provide the groundwork for the excitatory focus. Other investigators favor deafferentation of adjacent cortical neurons as the basis of their increased irritability.

**Treatment and Prophylaxis**  Usually the seizures can be controlled by a single anticonvulsant medication, and relatively few are recalcitrant to the point of requiring excision of the epileptic focus. In this small group, the surgical results vary according to the methods of patient selection and techniques of operation. Under the best of neurosurgical conditions three decades ago, with careful selection of cases, Rasmussen (also Penfield and Jasper) was able to eradicate seizures in 50 to 75 percent of cases by excision of the focus; the results currently are somewhat better.

The use of anticonvulsant drugs to prevent the first seizure and subsequent epilepsy has its proponents and opponents. In one study, patients receiving phenytoin developed fewer seizures at the end of the first year than a placebo group, but a year after medication was discontinued, the incidence was the same (and quite low) in the two groups. In another prospective double-blind study, one group of patients was given 60 mg phenobarbital and 200 mg phenytoin daily for 18 months and another group was untreated; at the end of 3- and 6-year periods, there was no significant difference in the occurrence of seizures between treated and untreated groups (Penry et al). Also, in a study of a large number of patients with penetrating head injuries, the prophylactic use of anticonvulsants was ineffective in preventing early seizures (Rish and Caveness), and this guides our own approach.

**Autonomic Dysfunction Syndrome in Traumatic Coma**  A troublesome consequence of severe head injury, observed most often in comatose patients and those in the persistent vegetative state, is the occurrence of episodic seizures combined with violent extensor posturing, profuse diaphoresis, hypertension, and tachycardia lasting minutes to an hour. A slight fever may accompany the spells. Families and staff are greatly disturbed by the display, particularly when accompanying grimacing suggests suffering. These spells of excessive sympathetic activity and posturing may be precipitated by painful stimuli or by distention of a viscus, but often they arise spontaneously. The syndrome is often mistakenly identified as a seizure and in many texts is still incorrectly referred to as “diencephalic epilepsy,” but it is more likely the result of the removal of suppressive cortical influences, allowing the hypothalamus to function independently of normal inhibitory mechanisms. A survey of 35 such patients by Baugley and colleagues identified diffuse axonal injury and a period of hypoxia as the main associated injuries, and this has been our experience as well. Narcotics and diazepines have a slightly beneficial effect, but bromocriptine, which may be used in combination with sedatives or with small doses of morphine, has been most effective according to Rossitch and Bullard.

**Extrapyramidal and Cerebellar Disorders Following Trauma**  The question of a causative relationship between cerebral trauma and the development of Parkinson disease has been a controversial issue for many years—usually with the conclusion that the condition does not exist and that any apparent relationship is superficial and coincidental. Most such patients probably had early symptoms of Parkinson disease, brought to light by the head injury. There are, however, rare cases, such as the one reported by Doder and colleagues, in which traumatic necrosis of the lenticular and caudate nuclei was followed, after a period of 6 weeks, by the onset of predominantly contralateral parkinsonian signs, including tremor, which progressed slowly and were unresponsive to L-dopa, and there are undoubted instances of parkinsonism following severe closed head injury and the vegetative state (Matsuda et al). An exception to these statements may be a parkinsonian syndrome in ex-boxers, as a manifestation of the “punch-drunk” syndrome (see below). Cerebellar ataxia is a rare consequence of cranial trauma unless the latter was complicated by cerebral anoxia (causing ataxia with myoclonus) or a by a hemorrhage strategically placed in the deep midbrain or cerebellum. When cerebellar ataxia is due to the trauma itself, it is frequently unilateral and the result of injury to the superior cerebellar peduncle. An ataxia or “apraxia” of gait may also reflect the presence of a communicating hydrocephalus (see below and Chap. 30).

**“Punch-Drunk” Encephalopathy (Dementia Pugilistica)**  The cumulative effects of repeated cerebral injuries, observed in boxers who had engaged in many bouts over a long period of time, constitute a type of head injury that is difficult to classify. What is referred to is the development, after many years in the ring (sometimes toward the end of the boxer’s career, more often within a few years of retirement), of dysarthric speech and a state of forgetfulness, slowness in thinking, and other signs of dementia. Movements are slow, stiff, and uncertain, especially those involving the legs, and there is a shuffling, wide-based gait. In other words, a parkinsonian and dementing syndrome emerges and sometimes a moderately disabling ataxia, but there is no mistaking these for idiopathic Parkinson disease. The plantar reflexes may be extensor on one or both sides. The EEG contains slow waves of theta and sometimes delta frequency. The clinical syndrome was reanalyzed by Roberts and colleagues, who found it present to some degree in 37 of the 224 professional boxers they examined. More recent studies have shown that in about one-half of all professional boxers, both active and retired, the CT scan discloses ventricular dilatation and/or sulcal widening and a cavum septi pellucidi (why the latter, which is a developmental anomaly, would be overrepresented in boxers is unclear). These abnormalities had been demonstrated many years before, by pneumoencephalography, and were found to be related to the number of bouts (Ross et al; Casson et al).

A thorough pathologic study of this disorder has been made by Corsellis and associates. They examined the brains of 15 retired boxers who had shown the punch-drunk syndrome and identified a group of cerebral changes that appear to explain the clinical findings. Mild to moderate enlargement of the lateral ventricles and thinning of the corpus callosum were present in all cases. Also, practically all of them showed a greatly widened cavum septi pellucidi and fenestration of the septal leaves. Readily identified areas of glial scarring were situated on the inferior surface of the cerebellar cortex. In these areas and well beyond them, Purkinje cells were lost and the granule cell layer was somewhat thinned. Surprisingly, cerebral cortical contusions were found in only a few cases. Notably absent also was evidence of previous hemorrhage. Of the 15 cases, 11 showed varying degrees of loss of pigmented cells of the substantia nigra and locus ceruleus, and many of the...
remaining cells showed the Alzheimer neurofibrillary change; Lewy bodies were not observed, however. The neurofibrillary changes were scattered diffusely through the cerebral cortex and brainstem but were most prominent in the mediolateral gray matter. Noteworthy was the absence of discrete senile plaques in this material; however, all cases showed extensive immunoreactive deposits of β-amylloid (“diffuse plaques”). In three boxers who developed a parkinsonian syndrome, Davie and colleagues found a reduction of N-acetylaspartate in the putamen and pallidum by protein magnetic resonance spectroscopy. This probably reflected a loss of neurons in these regions and was said by these authors to differentiate it from idiopathic Parkinson disease. The pathogenesis of the punch-drunk state remains unclear.

**Posttraumatic Hydrocephalus** This is an uncommon complication of severe head injury. Intermittent headaches, vomiting, confusion, and drowsiness are the initial manifestations. Later on, mental dullness, apathy, and psychomotor retardation are seen; by this time the CSF pressure may have fallen to a normal level (normal-pressure hydrocephalus). Postmortem examinations have demonstrated an adhesive basilar arachnoiditis. Since a similar syndrome is observed occasionally after the rupture of a saccular aneurysm with subarachnoid hemorrhage, the same mechanisms, i.e., blocking of the aqueduct and fourth ventricle by blood clot and basilar meningeal fibrosis, may also be operative in traumatic hydrocephalus. Response to ventriculoperitoneal shunt may be dramatic. Zander and Foroglou have had extensive experience with this condition and have written informatively about it.

**Posttraumatic Nervous Instability (Postconcussion Syndrome)**

This troublesome and frequent sequela of head injury has been mentioned above as well as in the chapter on headache (page 158). When the syndrome is protracted, neurologists are vexed by the condition—a problem intensified by worried patients and family. It has also been called the posttraumatic or post concussion syndrome, posttraumatic headache, traumatic neurasthenia (Symonds), and traumatic psychasthenia, among many other names. Headache is the central symptom, either generalized or localized to the part that had been struck. The headache is variously described as aching, throbbing, pounding, stabbing, pressing, or band-like and is remarkable for its variability. The intensification of the headache and other symptoms by mental and physical effort, straining, stooping, and emotional excitement has been mentioned earlier; rest and quiet tend to relieve it. Such headaches may present a major obstacle to convalescence. Dizziness, another prominent symptom, is usually not a true vertigo but a giddiness or light-headedness. The patient may feel unsteady, dazed, weak, or faint. However, a certain number of patients describe symptoms that are consonant with labyrinthine disorder. They report that objects in the environment move momentarily, and that looking upward or to the side may cause a sense of unbalance; labyrinthine tests may show hyporeactivity; far more often they disclose no abnormalities. McHugh found a high incidence of minor abnormalities by electroneystagmography both in concussed patients and in those suffering from whiplash injuries of the neck; but we find some of the data difficult to interpret. Exceptionally, vertigo is accompanied by diminished excitability of both the labyrinth and the cochlea (deafness), and one may assume the existence of direct injury to the eighth nerve or end organ.

These symptoms clear up in several weeks in the majority of patients. When the symptoms persist, however, the patient is intolerant of noise, emotional excitement, and crowds. Tenseness, restlessness, fragmentation of sleep, inability to concentrate, feelings of nervousness, fatigue, worry, apprehension, and an inability to tolerate the usual amount of alcohol complete the clinical picture. The resemblance of these symptoms to those of anxiety and depression and to other forms of “posttraumatic stress disorder” is quite apparent. In contrast to this multiplicity of subjective symptoms, memory and other intellectual functions show little or no impairment, although this has been disputed. Leininger et al, for example, found that most of their 53 patients who suffered minor head injury in traffic accidents performed less well than controls on psychologic tests (category test, auditory verbal learning, copying of complex figures). The fact that those who were merely dazed did as poorly as those who were concussed and that litigation was involved in some cases would lead one to question these results. A further discussion of cognitive sequelae is found below.

The syndrome of posttraumatic nervous instability complicates all types of head injury, mild and severe. Once established, it may persist for months or even years, and it tends to resist all varieties of treatment. Eventually, the symptoms lessen. Strangely, this syndrome is almost unknown in children. Characteristic also is the augmentation of both the duration and intensity of this syndrome by problems with compensation and litigation, suggesting a psychologic factor. In countries where these matters are a less prominent part of the social fabric, the occurrence of posttraumatic syndrome is far less frequent. The constitution of the patient appears to be important. Stable, athletic, tough-fibered individuals take a concussive injury in stride, while the sensitive, nervous, complaining types may be so overwhelmed by such an accident that they are unable to expel it from their minds. Environmental stress assumes importance as well, for if too much is demanded of the patient soon after injury, irritability, insomnia, and anxiety are enhanced. In this connection, an interesting experiment was conducted by Mittenberg and colleagues. A group of subjects with no personal experience or knowledge of head injury were asked to select from a list those symptoms that they would expect after a concussive head injury. They chose a cluster of symptoms virtually identical to that of the postconcussion syndrome.

An approach to treating such patients is given further on, in the section on treatment, under “Patients with Only Transient Unconsciousness.”

**Other Posttraumatic Cognitive and Psychiatric Disorders** In all patients with cerebral concussion injury, there remains a gap in memory (traumatic amnesia) spanning a variable period from before the accident to some point following it. This gap is permanent and is filled in only by what the patient is told. In addition, as stated in the introduction to this section, some degree of impairment of higher cortical function may persist for weeks (or be permanent) after moderate to severe head injuries, even after the patient has reached the stage of forming continuous memories. During the period of deranged mentation, the memory disorder is the most prominent feature; in that respect the state resembles the alcoholic form of the Korsakoff amnesic state and has some resemblance to the state of transient global amnesia (page 379). It has been repeatedly asserted that this amnesic state is a constant feature of every prolonged traumatic mental disorder, but to the authors it reflects in part the ease with which memory can be tested. With more careful testing, other cognitive disorders are evident. Concussed pa-
tients, during the period of posttraumatic amnesia, rarely confabulate and usually have an impaired ability to register events and information, an abnormality not ordinarily observed in patients entering the chronic phases of Korsakoff psychosis. Apart from disorientation in place and time, the head-injured patient also shows defects in attention as well as distractibility, perseveration, and an inability to synthesize perceptual data. Judgment may be mildly impaired, rarely severely, during the amnestic epoch. A perseverative tendency interferes with both action and thought.

As a general rule, the lower the score on the Glasgow Coma Scale immediately after injury (Table 35-1) and the longer the post-traumatic gap in the formation of memories (anterograde amnesia), the more likely the patient is to suffer permanent cognitive and personality changes. Abnormalities in these spheres were found in only 12 percent of head-injured patients who had been in coma for longer than 24 h (Sazbon et al). If respiration and motor function were normal (except for early decorticate posturing) and there was no extraneural trauma, 94 percent of the patients recovered. According to Jennett and Bond, patients with good recovery achieved their maximum degree of improvement within 6 months. Others have found that detailed and repeated psychologic testing over a prolonged period, even in patients with relatively minor cerebral injuries, discloses measurable improvement for as long as 12 to 18 months.

There are other mental and behavioral abnormalities of a more subtle type that remain as sequela to cerebral injury. As the stage of posttraumatic dementia recedes, the patient may find it impossible to work or to adjust to his family situation. Such patients continue to be abnormally abrupt, argumentative, stubborn, opinionated, and suspicious. Unlike the traumatic mental disorder described above, in which there is a certain uniformity, these traits vary with the patient’s age, constitution, past experience, and the environmental stresses to which he is subjected. Extremes of age are important. The most prominent behavioral abnormality in children, described by Bowman et al, is a change in character. They become impulsive, heedless of the consequences of their actions, and lacking in moral sense—much like those who had recovered from encephalitis lethargica. Some adolescents or young adults show the general lack of inhibition and impulsivity that one associates with frontal lobe disease. In the older person it is the impairment of intellectual functions that assumes prominence. In most instances these more severe behavioral changes can be traced to contusions in the frontal and temporal lobes.

The tendency is for all such symptoms to subside slowly though not always completely, even in those in whom an accident has provoked a frank outburst of psychosis (as may happen to a manic-depressive, paranoid schizophrenic, or neurotic patient). These forms of “traumatic insanity” were carefully analyzed for the first time by Adolf Meyer.

Hysterical symptoms that develop after head injury, both cognitive and somatic, appear to be more common than those following injury to other parts of the body. These symptoms are discussed in Chap. 56.

### Treatment

#### Patients with Only Transient Unconsciousness

Patients with an uncomplicated concussive injury who have already regained consciousness by the time they are seen in a hospital and have a normal neurological examination pose few difficulties in management. They should not be discharged until the appropriate examinations (CT scans, skull films, if necessary) have been made and the results prove to be negative. Also, the patient should not be released until the capacity for consecutive memories has been regained and arrangements have been made for observation by the family of signs of possible though unlikely delayed complications (subdural and epidural hemorrhage, intracerebral bleeding, and edema). Most such patients become mentally clear, have mild or no headache, and are found to have a normal neurocerebral examination. They do not require hospitalization or special testing, but in the current litigious climate of the United States, some form of brain imaging is nonetheless often performed. Acetaminophen may be prescribed for headache. Any increase in headache, vomiting, or difficulty arousing the patient should prompt a return to the emergency department.

The patients with persistent complaints of headache, dizziness, and nervousness, the syndrome that we have designated as posttraumatic nervous instability, are the most difficult to manage, as discussed above. A treatment program must be planned in accordance with the basic problem. If there is mainly an anxious depression, antidepressant medications—such as fluoxetine, paroxetine, or a tricyclic—are often useful. Simple analgesics, such as acetaminophen or nonsteroidal anti-inflammatory drugs, should be prescribed for the headache. Litigation should be settled as soon as possible. To delay settlement usually works to the disadvantage of the patient. Long periods of observation, repetition of a multitude of tests, and waiting only reinforce the patient’s worries and fears and reduce the motivation to return to work. Neuropsychologic tests may be useful in the group with persistent cognitive difficulty, but the results should be interpreted with caution, since depression and poor motivation will degrade performance.

#### Patients with Severe Head Injury

If the physician arrives at the scene of an accident and finds an unconscious patient, a quick examination should be made before the patient is moved. First it must be determined whether the patient is breathing and has a clear airway and obtainable pulse and blood pressure, and whether there is dangerous hemorrhage from a scalp laceration or injured viscera. Severe head injuries that arrest respiration are soon followed by cessation of cardiac function. Injuries of this magnitude are often fatal; if resuscitative measures do not restore and sustain cardiopulmonary function within 4 to 5 min, the brain is usually irreparably damaged. Oxygen should be administered. Bleeding from the scalp can usually be controlled by a pressure bandage unless an artery is divided; then a suture becomes necessary. Resuscitative measures (artificial respiration and cardiac compression) should be continued until they are taken over by ambulance personnel.

The likelihood of a cervical fracture-dislocation, which may be associated with any severe head injury, is the reason for taking precautions in immobilizing the neck and moving the patient, as outlined on page 1054. In the awake patient, neck pain calls attention to this complication. It should be recalled that even in the absence of a spinal fracture, the spinal cord may be threatened by the instability resulting from ligamentous injuries (posing the risk of subluxation). In the study of 292 patients with cervical injuries by Demetriades and colleagues, 31 (11 percent) showed subluxations without fracture and 11 (4 percent) had cord injuries with neither fracture nor subluxation. The combined use of standard
cervical spine films and cervical CT scanning detected all cervical injuries. After severe head or neck injury, it is therefore advisable also to obtain standard anteroposterior, lateral, and oblique neck films, with additional gentle flexion (20°) and extension (30°) views of the neck and a neck CT scan. If these are normal and there is little or no neck pain, the cervical collar is no longer required. If these studies cannot be obtained or if there is significant persistent pain or other neurologic findings induced by head movement, a cervical MRI is advisable.

In the hospital, the first step is to clear the airway and ensure adequate ventilation by endotracheal intubation if necessary. A careful search for other injuries must be made, particularly of the abdomen, chest, spine, and long bones. Chestnut et al., in analyzing the data from the Traumatic Coma Data Bank, found that sustained early hypotension (systolic blood pressure <90 mmHg) was associated with a doubling of mortality. If shock was present on admission to the emergency ward, the mortality was 65 percent. Although the hypotension that follows some injuries is a vasodepressor response and usually comes under control without pressor drugs, a large, unimpeded intraventricular line should be inserted. Persistent hypotension due to head injury alone is an uncommon occurrence and should always raise the suspicion of a ruptured viscus or thoracic or abdominal internal bleeding, extensive fractures, or trauma to the cervical cord. Initially, the infused fluid should be normal saline, avoiding the administration of excessive free water because of its adverse effect on brain edema. Oxygen should continue to be administered until it can be shown that the arterial oxygen saturation is normal without it.

A rapid survey can now be made, with attention to the depth of coma, size of the pupils and their reaction to light, ocular movements, corneal reflexes, facial movements during grimace, swallowing, vocalization, gag reflexes, muscle tone and movements of the limbs, predominant postures, reactions to pinch, and reflexes. Bogginess of the temporal or postauricular area (Battle sign), bleeding from the nose or ear, and extensive conjunctival edema and hemorrhage are useful signs of an underlying basal skull fracture. However, it should be remembered that rupture of an eardrum or a blow to the nose may also cause bleeding from these parts. Fracture of the orbital bones may displace the eye, with resulting strabismus; fracture of the jaw results in malocclusion and discomfort on attempting to open the mouth. If urine is retained and the bladder is distended, a catheter should be inserted and kept there. Temperature, pulse, respiration, blood pressure, arterial oxygen saturation, and state of consciousness should be checked and charted every hour. The Glasgow Coma Scale, mentioned above, has provided a practical means by which the state of impaired consciousness can be evaluated at frequent intervals (Table 35-1), but it should not be considered a substitute for a more complete neurologic examination. A deteriorating scale dictates a change in management.

CT scanning is of central importance at this juncture. A sizable epidural, subdural, or intracerebral blood clot is an indication for immediate surgery. The presence of contusions, brain edema, and displacement of central structures calls for measures to monitor progression of these lesions and to control intracranial pressure. These measures are best carried out in a critical care unit.

Management of Raised Intracranial Pressure It is the practice on some services to insert one of several available devices that permits continuous recording of intracranial pressure (ICP) in cases of moderate and severe head injury (Narayan et al). Pressure measurements through a lumbar puncture needle do not accurately reflect the ICP and increase the risk of a cerebellar or temporal lobe herniation. Nor do the neurologic signs that constitute the Glasgow Coma Scale reflect the pressure in the cranium. The arguments for and against monitoring the ICP have been addressed earlier (page 532). Our impression is that in comatose patients, monitoring of the ICP, at a minimum, prevents errors in fluid administration and refines all the other details of management, including the appropriate use of osmotic diuretics and the correct level of hyperventilation. In these respects, monitoring can be helpful. However, there are few critical data to support the routine use of ICP monitoring; certainly the patient who is only drowsy or shows only minimal mass effect on CT scanning is not likely to be of benefit. In the absence of data to help in making the decision regarding the insertion of these devices, as a practical guide we favor their use to warn of impending deterioration from brain edema or hemorrhage if the patient shows sustained drowsiness with inability to follow commands, has a Glasgow Coma Scale score of <8, and has evidence of mass effect on a CT scan. The current generation of ICP monitors employs fiberoptic strain gauges that can be inserted directly into the cerebral cortex without apparent damage. While the risk of infection is low, prolonged use may be complicated by bacterial meningitis. The monitor is left in place for 3 to 5 days or less if the clinical state and ICP are stable for 24 to 48 h.

The first step in lowering high ICP is to control the incidental factors that are known to raise the pressure, such as hypoxia, hypercarbia, hyperthermia, awkward head positions that compress the jugular veins, and high mean airway pressures (see the monograph by Ropper and colleagues). If the intracranial pressure exceeds 15 to 20 mmHg, several measures can be instituted, such as inducing hypocarbia by controlled ventilation (maintaining PCO₂, at 28 to 33 mmHg) and hyperosmolar dehydration (0.25 to 1.0 g of 20% mannitol every 3 to 6 h or 0.75 to 1 mg/kg of furosemide, see below) to maintain serum sodium above 138 meq/L and an osmolality of 290 to 300 mosmol/L. Even if ICP monitoring is not utilized, an attempt should be made to maintain this level of osmolality for the first days if contusion and brain swelling are detected on the CT scan. Elevations in osmolality due to excessive concentrations of diffusible solutes such as glucose are not useful in reducing intracranial volume because they do not provide a water gradient across the cerebral vasculature. For this reason, the measurement of serum sodium is in some ways a more accurate reflection of free water depletion. An initial sodium level of 136 to 141 meq/L is adequate. Intravenous fluids with free water should be avoided as not to intensify cerebral edema. This poses a particular danger in children who, because of inappropriate secretion of antidiuretic hormone, easily develop water intoxication. With this exception, however, restriction of the overall volume of fluid is less of a concern than effecting a reduction in free water. Fluids such as 5% dextrose in water, 0.5% saline, and 5% dextrose in 0.5% saline are therefore avoided; lactated Ringer’s solution is permissible; normal saline, with or without added dextrose, is ideal.

The effects of mannitol have been of great interest to neurosurgeons who treat head trauma, but the best plan for its use has never been established. Among the randomized studies that provide clinical data, only the one by Cruz and colleagues has demonstrated a clear benefit and particularly in relation to acute subdural hematoma. These authors administered mannitol in a bolus, 0.6 g/kg, to all patients immediately, and then, once a subdural hematoma was identified by CT scan, gave an additional similar second dose to those with reactive pupils and twice the original dose to those with unreactive pupils or anisocoria. Benefits were obtained...
in these patients and another study of patients with temporal lobe contusion by the same investigators. In the end, it must be concluded that large boluses of mannitol are beneficial in closed head injury, especially if there is an acute subdural hematoma or contusions, and this may extend to patients who have pupillary abnormalities. Hypertonic saline (3 percent) probably has a comparable effect to mannitol in the treatment of acutely raised ICP.

Hypocarbia, induced by hyperventilation, is effective in reducing ICP for only a limited period of time, since the pH of the spinal fluid equilibrates over hours and allows cerebral blood volume to return to its previous level. A single-step reduction in PCO₂ typically lowers ICP for approximately 20 to 40 min. Attempts to prolong the effect of hypocarbia and the alkalosis by the intravenous administration of ammonium buffers have met with mixed success. It has even been suggested that hyperventilation may be harmful to some head-injured patients because of a reduction in cerebral blood flow, but the risk, if any, appears to be minimal. For these reasons, hypocarbia is not often used in cases of head trauma. The method of deep cooling has had its proponents over the years, but most attempts to demonstrate improved outcome have been unsuccessful (see Clifton et al). Lowering of the body temperature will, however, transiently reduce ICP.

If the ICP continues to rise and brain swelling progresses despite these measures, the outlook for survival is bleak. Hypothermia and barbiturate anesthesia to reduce ICP have been used, but relatively few patients respond to such measures for long. A randomized controlled trial of cooling patients with severe closed head injury (Glasgow Coma Scale scores of 3 to 7) to 33°C for 24 h appeared to hasten neurologic recovery and may have modestly improved outcome (Marion et al). Since on rewarming, however, there may be a rapid increase in ICP, the body temperature must be raised very gradually over a day or more. It has been suggested by Shann, who has summarized the many trials of hypothermic treatment, that most were unlikely to show benefit because the degree and duration of cooling were inadequate. Barbiturates, while they lower ICP, may lower the blood pressure as well; hence they may diminish cerebral perfusion. However, Marshall and coworkers claimed a high rate of improvement and survival by using barbiturates even in cases where the ICP exceeded 40 mmHg. The more definitive randomized study by Eisenberg and associates showed no benefit from barbiturate-induced anesthesia in head-injured patients. Several large controlled studies have established that the administration of high-dose steroids does not significantly affect the clinical outcome of severe head injuries. Consequently, their use has been abandoned except for cases of marked edema surrounding a contusion or hematoma; even then, the benefit is uncertain (Gudeman et al; Dearden et al; Braakman et al; Saul et al). The use of wide decompression craniectomy in cases of intractable brain swelling is commented on below.

The management of posttraumatic systemic hypertension can be a difficult problem. Immediately after head injury, the sympathoadrenal response and elevation of blood pressure will recede spontaneously in a matter of a few hours or days. Unless the blood pressure elevation is extreme (greater than 180/95 mmHg), it can be disregarded in the early stages. In animal experiments, it has been found that severe hypertension leads to increased perfusion of the brain and an augmentation of the edema surrounding contusions and hemorrhages. As mentioned earlier, edema is the main element in the genesis of brain swelling and of raised ICP in most head-injured patients (Marmarou et al). This reflects a failure of autoregulatory vascular mechanisms, with resulting transudative edema in damaged areas of the brain. The control of high blood pressure must be balanced against the risk of reducing cerebral perfusion pressure and the observation that even a brief period of mild hypotension may provoke a cycle of cerebral vasodilation, increased cerebral blood volume, and elevated ICP in the form of plateau waves (Rosner and Becker). Observations such as these emphasize the need for immediate and vigorous management of hypotension in severely head-injured patients.

Since most therapies for elevated ICP dehydrate the patient or reduce cardiac filling pressures, thereby leading to hypotension, a middle course, of avoiding both severe hypotension and any degree of hypotension, seems the best compromise. In lowering high levels of blood pressure, diuretics, beta-adrenergic blocking agents, or angiotensin converting enzyme inhibitors should be used, rather than agents that may dilate the cerebral vasculature (nitroglycerin and nitroprusside, hydralazine, and some of the calcium channel blockers). Hypotension should be corrected by vasopressor agents such as norepinephrine. The precise level of blood pressure that requires treatment must be judged in the context of the ICP and the presence of plateau waves (the goal being to maintain normal cerebral perfusion) as well as the patient’s previous blood pressure level; evidence of organ failure, such as cardiac or renal ischemia, must also be taken into account.

**General Medical Measures** If coma persists for more than 48 h, a nasogastric tube should be passed and fluids and nutrition given by this route. Agents that reduce gastric acid production—or the equivalent, antacids by stomach tube to keep gastric acidity at a pH above 3.5—are of value in preventing gastric hemorrhage. The prophylactic use of anticonvulsant drugs, as discussed earlier, under “Posttraumatic Epilepsy,” has recently been favored, but there is no evidence that delayed epileptic seizures are reduced (see Chand and Lowenstein). Only if there has been a seizure are anticonvulsants given.

Restlessness is controlled by diazepam or a similar sedative, but only if careful nursing fails to quiet the patient and provide sleep for a few hours at a time. Haloperidol is usually avoided in the acute stage. Fever is counteracted by antipyretics such as acetaminophen, and, if necessary, by a cooling blanket. The use of morphine or bromocriptine to quiet episodes of vigorous extensor posturing and accompanying adrenergic activity has already been mentioned.

**Surgical Measures** The need for surgical intervention during the acute posttraumatic period is decided by two factors: the clinical status of the patient and CT scanning. The presence of a subdural or epidural clot that is causing a shift of central brain structures calls for its immediate evacuation. The approach to subdural hematomas has been discussed earlier in this chapter. Should the elevated ICP not respond to this procedure or to the standard osmotic agents and other medical measures outlined above, or should the condition of the patient and vital signs then begin to deteriorate (pulse rising, temperature rising or falling below normal, state of consciousness worsening, hemiplegia more obvious, plantar reflexes more clearly extensor), a renewed search must be undertaken for a late-occurring cerebral mass. Usually in these clinical circumstances, CT scanning will disclose a new or enlarged epidural, subdural, or intracerebral hematoma, marked cerebral edema, and a lateral shift of central cerebral structures. **If death or severe disability is to be avoided, operation in these cases must be undertaken before the advanced signs of brainstem compression—de-**
A hemiplegia is often reduced to a minimal hemiparesis or to an and penetrating ones, tend always to ameliorate as the months pass. These authors were of the opinion that these results represented a significant improvement over the expected outcome in this particular group of patients. Similar results in children have been reported by Polin et al. The few cases with which we have been involved, mostly children operated late, have not been as encouraging, but the procedure deserves further evaluation, especially in younger patients.

The treatment of other problems attendant on protracted coma has been outlined in Chap. 17. Each patient presents unique problems that must be dealt with individually.

**PROGNOSIS**

In respect to severe head injury, as has been intimated, the outcome is particularly discouraging. Some aspects of prognosis have been mentioned earlier but the following general comments serve to frame the problem. In the survey of the large European Brain Injury Consortium, comprising 10,005 adult patients, the injury proved fatal in 31 percent; 3 percent were left in a persistent vegetative state, and 16 percent remained severely disabled neurologically (Murray et al). Data from the extensively analyzed Traumatic Coma Data Bank are comparable (Marshall et al). The signs of focal brain disease, whether due to closed head injuries or to open and penetrating ones, tend always to ameliorate as the months pass. A hemiplegia is often reduced to a minimal hemiparesis or to an ineptitude of voluntary motor function with exaggerated reflexes and an equivocal Babinski sign on that side, and an aphasia is gradually transformed into a stuttering or hesitant paraphasia or dysnomia that is not disabling except to a professional person, speaker, or writer. Many of the signs of brainstem disease (cranial nerve dysfunction and ataxia) improve also, usually within the first 6 months after injury (Jennett and Bond) and often to a surprising extent. Most patients who had been in coma for many hours or days—i.e., those with severe brain injuries—are left with memory impairment and other cognitive defects and with personality changes. These may be the only lasting sequelae. According to Jennett and Bond, these mental and personality changes are a greater handicap than focal neurologic ones as far as social adjustment is concerned. In open head wounds and penetrating brain injuries, Grafman and coworkers found that the magnitude of tissue loss and location of the lesion were the main factors affecting the outcome.

The prognosis of head injury is influenced by several other factors. The *age of the patient* is the most important of these (Vollmer et al). Increasing age reduces the chances of survival and of good recovery. Older patients often remain disabled, especially when compensation is involved. Young and middle-aged ones do better, particularly if they are not entitled to compensation. Russell has pointed out that the severity of the injury as measured by the duration of traumatic amnesia is a useful prognostic index. Of patients with a period of amnesia lasting less than 1 h, 95 percent were back at work within 2 months; if the amnesia lasted longer than 24 h, only 80 percent had returned to work within 6 months. However, about 60 percent of the patients in his large series still had symptoms at the end of 2 months, and 40 percent at the end of 18 months. Of the most severely injured (those comatose for several days), many remained permanently disabled. However, the degree of recovery was often better than one had expected; the motor impairment, aphasia, and dementia tended to lessen and sometimes cleared. Improvement could continue over a period of 3 or more years. Children seemed to recover more completely than adults.

MULTIPLE SCLEROSIS AND ALLIED DEMYELINATIVE DISEASES

It has long been the practice to set apart a group of diseases of the brain and spinal cord in which destruction of myelin (demyelination) is a prominent feature. To define these diseases precisely is difficult, for the simple reason that there is probably no disease in which myelin destruction is the exclusive pathologic change. The idea of a demyelinating disease is, more or less, an abstraction that serves primarily to focus attention on one of the more striking and distinctive features of one group of pathologic processes.

The commonly accepted pathologic criteria of a demyelinating disease are (1) destruction of the myelin sheaths of nerve fibers with relative sparing of the other elements of nervous tissue, i.e., of axons, nerve cells, and supporting structures, as reflected by a relative lack of wallerian or secondary degeneration of fiber tracts; (2) infiltration of inflammatory cells in a perivascular and particularly paravenous distribution; (3) a distribution of lesions that is primarily in white matter, either in multiple small disseminated foci or in larger foci spreading from one or more centers.

A classification of the demyelinating diseases is presented in Table 36-1. The diseases included in this classification conform approximately to the criteria enumerated above. Like all classifications that are not based on etiology, this one has its shortcomings in that it is somewhat arbitrary. In some of the diseases here classified as demyelinating, notably Schilder disease and necrotizing hemorrhagic leukoencephalitis and even multiple sclerosis, there can be a severe degree of damage to axis cylinders and vascular structures as well as to myelin. Contrariwise, a number of diseases in which demyelination is a prominent feature are not included. In some cases of anoxic encephalopathy, for example, the myelin sheaths of the radiating nerve fibers in the deep layers of the cerebral cortex or in ill-defined patches in the convolutional and central white matter are destroyed, while most of the axis cylinders are spared. A relatively selective degeneration of myelin may also occur in some small ischemic foci due to vascular occlusion or in larger confluent areas, as is the case in Binswanger disease (see Chap. 34). In subacute combined degeneration (SCD) of the spinal cord associated with pernicious anemia and in tropical spastic paraparesis (TSP), a demyelinating spinal cord disease, myelin may be affected earlier and to a greater extent than axis cylinder. The same is true of progressive multifocal leukoencephalopathy (PML), central pontine myelinolysis, and Marchiafava-Bignami disease. Some of these disorders and several others are no longer classified as demyelinating because their etiology has been established. Also, for reasons that will become clear in subsequent discussion, the chronic progressive leukodystrophies of childhood and adolescence (e.g., globoid body, metachromatic, and adrenal leukodystrophies), while clearly diseases of myelin, are set apart and called dysmyelinating because of their unique genetic and morphologic features and are discussed in Chap. 37. Occupying an uncertain place in this nosology are demyelinating lesions associated with connective tissue diseases or merely with autoantibodies directed against DNA or phospholipids. Again, the central nervous system (CNS) lesions may be multiple and cannot easily be distinguished radiologically from multiple sclerosis (MS). But, as noted further on, their nature is uncertain, and some are clearly due to a vasculopathy. Excluded from discussion in this chapter are demyelinating diseases of the peripheral nerves. Although they share a number of pathologic features with demyelinating diseases of the CNS, they are described with diseases of the peripheral nervous system in Chap. 46.

In the language of neurology, therefore, the term demyelination has acquired a special meaning; if it is to retain its value, it should be used in the restricted sense indicated above and not as a synonym for any destructive process of nerve fibers or cerebral white matter or for inherent and inherited defects in myelin, even though the lesions may look alike in a section stained for myelin.

Multiple sclerosis, called “MS” by most physicians, is referred to by the British as disseminated sclerosis and by the French as sclérose en plaques. It is among the most venerable of neurologic diseases and one of the most important by virtue of its frequency, chronicity, and tendency to attack young adults. It is a chronic condition characterized clinically by episodes of focal disorders of the optic nerves, spinal cord, and brain, which remit to a varying extent and recur over a period of many years. The neurologic manifestations are protean, being determined by the varied location and extent of the demyelinating foci; nevertheless, the lesions have a predilection for certain parts of the CNS, resulting in complexes of symptoms and signs and radiologic appearances that can often be recognized as characteristic of MS.

Table 36-1
Classification of the demyelinating diseases

| I. Multiple sclerosis (disseminated sclerosis) |
| A. Chronic relapsing encephalomyelopathic form |
| B. Acute multiple sclerosis |
| C. Diffuse cerebral sclerosis (Schilder disease and concentric sclerosis of Balo) |
| II. Neuromyelitis optica (Devic disease) |
| III. Acute disseminated encephalomyelitis |
| A. Postinfectious: following measles, chickenpox, smallpox, mumps, rubella, influenza, and other viral and some bacterial infections (Mycoplasma, Rickettsia) |
| B. Following rabies or smallpox and rarely other types of vaccination (postvaccinal) |
| IV. Acute and subacute necrotizing hemorrhagic encephalitis |
| A. Acute encephalopathic form (Hurst hemorrhagic leukoencephalitis) |
| B. Subacute necrotic myelopathy |
Classic features include motor weakness, paraparesis, paresthesias, loss of sight, diplopia, nystagmus, dysarthria, intention tremor, ataxia, impairment of deep sensation, and bladder dysfunction. The diagnosis may be uncertain at the onset and in the early years of the disease, when symptoms and signs point to a lesion in only one locus of the nervous system. Later, as the disease recurs and disseminates throughout the cerebrospinal axis, diagnostic accuracy approaches 100 percent. A long period of latency (1 to 10 years or longer) between a minor initial symptom, which may not even come to medical attention, and the subsequent development of more characteristic symptoms and signs may delay the diagnosis. In most cases there is a relapsing-remitting pattern, i.e., the initial manifestations improve partially or completely, to be followed after a variable interval by the recurrence of the same abnormalities or the appearance of new ones in other parts of the nervous system. However, in fewer than half of patients, the disease takes the form of an intermittently progressive illness (relapsing-remitting, the typical type of MS), and sometimes of a steadily progressive one, especially in patients more than 40 years of age at the time of onset (primary progressive MS). Or, as happens more often, an initially relapsing profile later becomes steadily progressive (secondary progressive MS). Some data are accumulating to suggest that the pathogenesis of the chronic progressive, nonremitting type (see further on). However, further study will be required to determine whether these perspectives are valid or the differences between these two extremes may be different from that of the relapsing-remitting cases, but in the authors’ opinion this is still questionable.

A rule that has guided clinicians for many years is that the diagnosis of MS is not secure unless there is a history of remission and relapse and evidence on examination of more than one discrete lesion of the CNS. The advent of certain ancillary procedures—notably magnetic resonance imaging (MRI) and evoked potentials—and their capacity to identify clinically inapparent lesions—has obviated the exclusive dependence on clinical criteria for the diagnosis.

Pathologic Findings

Before being sectioned, the brain generally shows no evidence of disease, but the surface of the spinal cord may appear and feel uneven. Sectioning of the brain and cord discloses numerous scattered patches where the tissue is slightly depressed below the cut surface and stands out from the surrounding white matter by virtue of its pink-gray color (due to loss of myelin). The lesions may vary in diameter from less than a millimeter to several centimeters; they affect principally the white matter of the brain and spinal cord and do not extend beyond the root entry zones of the cranial and spinal nerves. It is because of their sharp delineation that they were called plaques by French pathologists.

The topography of the lesions is noteworthy. A periventricular localization is characteristic, but only where subependymal veins line the ventricles (mainly adjacent to the bodies and atria of the lateral ventricles). Other favored structures are the optic nerves and chiasm (but rarely the optic tracts) and the spinal cord, where pial veins lie next to or within the white matter (Fig. 36-1; see also “MRI in MS,” page 783). The lesions are distributed randomly throughout the brainstem, spinal cord, and cerebellar peduncles without reference to particular systems of fibers but always confined predominantly to the white matter. In the cerebral cortex and central nuclear and spinal structures, the acute lesions destroy myelin sheaths but leave the nerve cells essentially intact. Severe and more chronic lesions, however, may destroy axons and neurons in the affected region, but the essential lesion is still demyelinating.

The histologic appearance of the lesion depends on its age. Relatively recent lesions show a partial or complete destruction and loss of myelin throughout a zone formed by the confluence of many small, predominantly perivenous foci; the axons in the same region are relatively spared or less affected. There is a variable but only slight degeneration of oligodendroglias, a variable neuroglial (astrocytic) reaction, and perivascular and para-adventitial infiltration with mononuclear cells and lymphocytes. Later, large numbers of microglial phagocytes (macrophages) infiltrate the lesions, and astrocytes in and around the lesions increase in number and size. Long-standing lesions, on the other hand, are composed of thickly matted, relatively acellular fibroglial tissue, with only occasional perivascular lymphocytes and macrophages; in such lesions, a few intact axis cylinders may still be found. Sparing of axis cylinders (axons) prevents wallerian degeneration. However, in old lesions with interruption of axons, there may be descending and ascending degeneration of long fiber tracts in the spinal cord. Partial remyelination is believed to take place on undamaged axons and to account for partially demyelinated “shadow patches” (Prineas and Connell). A few of the most severe older lesions will have undergone cavitation, indicating that the disease process has affected not only myelin and axons but also supporting tissues and blood vessels as well. All gradations of histopathologic change between these two extremes may be found in lesions of diverse size, shape, and age, consistent with the extended clinical course. This emphasis on the pathologic destruction of myelin obscures the central fact that the immune system effects this change, the myelin itself being normal in the structure and immune composition.

An insight into the complexity of the immunopathologic process can be appreciated in a recent microscopic analysis by Lucchinetti and colleagues (2000) of 83 autopsy and brain biopsy specimens from patients with MS. They categorized several distinct histologic subgroups. In most, the inflammatory response was distinguished by extensive perivenular deposition of immunoglobulin and complement, suggesting a role for a humoral pathogenesis. In others, inflammation was present only at the periphery of plaques and the distinctive feature was a marked apoptosis of oligodendrocytes. In yet another group, perhaps the end stage of the last one described, there was nearly complete loss of oligodendrocytes without apoptosis and an absence of remyelination. Two features are of interest here. First, each case demonstrated only one pattern of pathology, suggesting that perhaps different pathophysiologic processes operated in each patient. Moreover, the last two histopathologic types were considered to represent a primary oligodendroglial degeneration. A possible confirmation of the primary process in oligodendrocytes is the material from newly symptomatic lesions reported by Barnett and Prineas. In 7 of 12 cases there were some lesions with oligodendrocyte apoptosis and microglial activation but without an inflammatory or macrophage response. Aside from this novel idea regarding the oligodendrocytes, the overall implication is that the pathologic characteristics of the chronic progressive type of MS may differ from those of the typical relapsing type (see further on). However, further study will be required to determine whether these perspectives are valid or the differences simply reflect limited sampling, the age of the plaque, or the severity of an immune process. At the moment, the authors regard observations of a primary role for oligodendrocyte destruction to be provisional and continue to conceptualize MS as an inflammatory-immune process that targets central myelin along the lines of the observations of Adams and Kubik in their earlier studies.
Etiology and Epidemiology

Cruveilhier (circa 1835), in his original description of the disease, attributed it to suppression of sweat, and since that time there has been endless speculation about the etiology. Many of the early theories appear ludicrous in the light of present-day concepts, and others are of mainly historical interest. There is little point in enumerating them here; complete accounts are to be found in the reviews of DeJong (1970), Prineas (1970), R. T. Johnson (1978), and McDonald (1986).

Although the precise cause of MS remains undetermined, a number of epidemiologic facts have been clearly established and will eventually have to be incorporated in any etiologic hypothesis. The disease has a prevalence of less than 1 per 100,000 in equatorial areas; 6 to 14 per 100,000 in the southern United States and southern Europe; and 30 to 80 per 100,000 in Canada, northern Europe, and the northern United States. More recently, Mayr and colleagues reported an incidence of 8 and a prevalence of 177 cases per 100,000 in Olmstead County, MN; this prevalence has been stable for approximately 30 years. A less well defined gradient
exists in the Southern Hemisphere. Kurland’s studies indicate that there is a threefold increase in prevalence and a fivefold gradient in mortality rate between New Orleans (30 degrees north latitude), on the one hand, and Boston (42 degrees north) and Winnipeg (50 degrees north) on the other. In Japan there is a similar though less distinct geographic gradient (the prevalence of MS there is much lower than in corresponding latitudes of North America and northern Europe).

The increasing risk of developing MS with increasing latitude has been confirmed by J. B. Barlow and Kurtzke and associates. The latter studied a series of unprecedented size (5305 undoubted cases of MS and matched controls). They showed also that in the United States, African Americans are at lower risk than whites at all latitudes, but both races show the same south-to-north gradient in risk, probably indicating the importance of an environmental factor regardless of race. Supporting this view are the descriptions, by Kurtzke and Hyllested, of an “epidemic” of MS in the Faroe Islands of the North Atlantic. They found a much higher than expected incidence of the disease, occurring as three separate outbreaks of decreasing extent between the years 1943 and 1973. (It should be pointed out that the largest outbreak consisted of only 21 cases.) It was their contention, confirmed by Poskanzer, that the disease was due possibly to an unidentified infection introduced by British troops who occupied the islands in large numbers in the years immediately preceding the outbreak. Kurtzke and colleagues have also described a similar postwar epidemic in Iceland.

Several studies indicate that persons who migrate from a high-risk to a low-risk zone carry with them at least part of the risk of their country of origin, even though the disease may not become apparent until 20 years after migration. Such a pattern has been demonstrated in both South Africa and Israel. Dean determined that the prevalence of MS in native-born white South Africans was 3 to 11 per 100,000, whereas the rate in immigrants from northern Europe was about 50 per 100,000, only slightly less than among the nonimmigrating natives of those countries. The data of Dean and Kurtzke indicate further that in persons who had immigrated before the age of 15, the risk was similar to that of native-born South Africans; whereas in persons who had immigrated after that age, the risk was similar to that of their birthplace. Alter and colleagues found that in the descendants of European immigrants born in Israel, the risk of MS was low, similar to that of other native-born Israelis, whereas among recent immigrants the incidence in each national group approached that of the land of birth. Again, the critical age of immigration appeared to be about 15 years. These epidemiologic studies and others have shown that MS is associated with particular localities rather than with a particular ethnic group in those localities and again implicate environmental factors in the genesis of the disease.

Also, a familial aggregation of MS is now well established. About 15 percent of MS patients have an affected relative, with the highest risk of concurrence being observed in the patient’s siblings (Ebers, 1983). In a large population-based study carried out in British Columbia by Sadovnick and colleagues, it was found that almost 20 percent of index cases had an affected relative, again with the highest risk in siblings. In a subsequent study, Sadovnick and colleagues sought to determine the degree of heritability of MS by comparing the risk of disease in the half-sibs (one biologic parent in common) of affected individuals with the risk in full sibs; the risk for full sibs was two to three times greater than for half-sibs and they interpreted these results as largely genetic in basis.

The case for heritability is supported by studies of twins in whom one of each pair is known to have MS. In the most extensive of these studies (Ebers et al), the diagnosis was verified in 12 of 35 pairs of monozygotic twins (34 percent) and in only 2 of 49 pairs of dizygotic twins (4 percent). Furthermore, in two additional sets of monozygotic twins who were clinically normal, lesions were detected by MRI. The concordance rate in dizygotic pairs is similar to that in non-twin siblings. Despite these provocative findings, no consistent pattern of mendelian inheritance has emerged. (Of course, one must not assume that all diseases with an increased familial incidence are hereditary in that instances of the same condition in several members of a family may simply reflect an exposure to a common environmental agent. Paralytic poliomyelitis, for example, was about eight times more common in immediate family members than in the population at large.)

Nonetheless, further evidence of a genetic factor in the causation of MS is the finding that certain histocompatibility locus antigens (HLAs) are more frequent in patients with MS than in control subjects. The strongest association is with the DR locus on the sixth chromosome. Other HLA haplotypes that are overrepresented in MS (HLA-DR2 and, to a lesser extent, -DR3, -B7, and -A3) are thought to be markers for an MS “susceptibility gene”—possibly an immune response gene. The presence of one of these markers increases the risk that an individual will develop MS by a factor of 3 to 5. These antigens may indeed prove to be related to the frequency of the disease, but their presence is not invariably and their exact role is far from clear (see Compston).

The low conjugal incidence of MS, on the other hand, indicates that any common exposure to an infecting infection or environmental agent must occur early in life. In order to test this hypothesis, Schapira and coworkers determined the periods of common exposure (common habitation periods) in members of families with two or more cases. From this they calculated the mean common exposure to have happened before 14 years of age, with a latency of about 21 years—figures that are in general agreement with those derived from the migration studies quoted above.

The incidence of MS is two or three times higher in women than in men, but the significance of this fact is unclear, the best current explanation being that women are generally more susceptible to immune and inflammatory conditions. The incidence in children is very low; only 0.3 to 0.4 percent of all cases appear during the first decade. In an analysis of three childhood-onset cases, Hauser and colleagues found no phenotypic differences between childhood and adult cases. Beyond childhood, the risk of first developing symptoms of the disease rises steeply with age, reaching a peak at about 30 years, remaining high in the fourth decade, then falling off sharply and becoming low in the sixth decade. It has been pointed out that MS has a unimodal age-specific onset curve, similar to the age-specific onset curves of many infectious and connective tissue diseases.

About two-thirds of cases of MS have their onset between 20 and 40 years of age. Of the remainder, most cases begin before the age of 20; in a smaller number, the disease appears to develop in late adult life (late fifties and sixties). In the latter patients, early symptoms may have been forgotten or may never have declared themselves clinically (we have several times found the typical lesions of MS in aged autopsied individuals who had no history of neurologic illness). Gilbert and Sadler report five such cases and from their pathologic findings declare that the true incidence of MS may be three times higher than stated figures.

Several studies from northern Europe and Canada have suggested that the likelihood of developing MS is somewhat greater.
among rural than among urban dwellers; studies of American army personnel indicate the opposite (Beebe et al). A number of surveys in Great Britain have intimated that the disease is more frequent in the higher socioeconomic groups than in the lower ones. Yet in the United States, no clear relationship has been established to the poverty or social deprivations that are part of a low socioeconomic status. Numerous other environmental factors [surgical operations, trauma, anesthesia, exposure to household pets (small dogs), mercury in silver amalgam fillings in teeth] have been proposed but are unsupported by firm evidence and probably are mostly spurious associations.

Pathogenesis

These epidemiologic data point to both a genetic susceptibility and some environmental factor that is encountered in childhood and, after years of latency, evokes the disease. In recent years, speculation has grown that this factor is an infection, most often viral. A body of indirect evidence has been marshaled in support of this idea, based largely on alterations in humoral and cell-mediated immunity to viral agents (see reviews of R. T. Johnson, Lampert, K. P. Johnson et al, McFarlin and McFarland). However, to this community to viral agents (see reviews of R. T. Johnson, Lampert, K. P. Johnson et al, McFarlin and McFarland). However, to this day no virus (including all known members of the human retrovirus family) has been seen in or isolated from the tissues of patients with MS despite innumerable attempts to do so. Moreover, no satisfactory viral model of MS has been produced experimentally. Recently, the bacterial agents Chlamydia pneumoniae and Borrelia burgdorferi (the agent of Lyme disease) and herpesvirus type 6 have been similarly implicated by the finding of their genomic material in MS plaques, but the evidence for their direct participation in the disease is, at the moment, not compelling.

If indeed some obscure infection is the initial event in the genesis of MS, then a secondary factor must be operative in later life to reactivate the neurologic disease and cause exacerbations. One popular view is that this secondary mechanism is an autoimmun reaction, attacking some component of myelin and, in its most intense form, destroying all tissue elements, including axons. Several lines of argument have been advanced in support of this view. One is inclined to draw an analogy between the lesions of MS and those of acute disseminated encephalomyelitis, which is almost certainly an autoimmune disease of delayed hypersensitivity type (see further on). In support of this possibility is the finding of antibodies to specific myelin proteins—e.g., myelin basic protein (MBP)—in both the serum and cerebrospinal fluid (CSF) of MS patients, and these antibodies, along with T cells that are reactive to MBP and to other myelin proteolipids, increase with disease activity; moreover, MBP cross-reacts to some extent with measles virus antibodies. The arguments that a chronic viral infection re-activates and perpetuates the disease are, however, less convincing than those proposing a role for viruses in the initiation of the process in susceptible individuals.

A possible way in which viral infections and autoimmune reactions in the nervous system might be linked to the abnormal expression of autoantigens on CNS cells has been suggested by R. T. Johnson. He found that several different viruses (rubeola, rubella, varicella) could cause the sensitization of T lymphocytes against myelin basic protein. This implies that the T lymphocyte recognizes an identical structure in both the virus and the myelin sheath. The hypothesis continues with the notion that once the autoimmune process is initiated by a virus in childhood, it can later be reactivated by any of the common viral infections to which the individual is exposed, particularly in the far higher northern and southern latitudes. This phenomenon of “molecular mimicry” (a shared antigen between the virus and CNS myelin, the oligodendrocyte, or cerebral vessels) has been invoked as a mechanism in several diseases, notably in rheumatic fever, certain paraneoplastic diseases, and Guillain-Barré syndrome, but remains speculative in MS.

The role of humoral and cellular factors in the production of MS plaques is not fully understood. The deposition of immunoglobulin in the plaques of patients with acute and relapsing-remitting disease, but not those with progressive MS, has been alluded to earlier. That the humoral immune system is involved is evident from the presence in the CSF of most patients of oligoclonal immune protein antibodies, which are produced by B lymphocytes within the CNS. Sera from patients with MS (and some normal controls), when added to cultures of nervous system tissue from newborn mice in the presence of complement, can damage myelin, inhibit remyelination, and block axonal conduction. Antibodies to oligodendrocytes are present in the serum of up to 90 percent of patients in some studies but far less frequently in others. Of note also are the findings of Berger and colleagues that show a relationship between the clinical progression of early and monosymptomatic MS and the presence of serum autoantibodies against oligodendrocyte glycoprotein and myelin basic protein. They have reported that the absence of antibodies, a finding in 38 percent of their patients, identified a group with more benign disease, at least for several years. Whether this further indicates, as they suggest, that humoral immune mechanisms are essential to the production of MS is uncertain.

Autoantibodies have been found that are directed against myelin oligodendrocyte glycoprotein (MOG) and myelin basic protein (MBP). It has also been demonstrated that subsets of T cells (CD41 Th2 cells) are activated by MBP and MOG to activate B cells, the production of oligoclonal bands and membrane attack complexes, and the release of cytokines [tumor necrosis factor alpha (TNF-α), interleukins, interferon gamma (IFN-γ)]. The inflammatory process erodes the blood-brain barrier and ultimately destroys both oligodendroglia and axons. The eventual functional outcome reflects both the activity of this inflammatory cascade and the degree of axonal damage. In other cases, there may be a compromise of oligodendroglial function and axonal degeneration in the absence of prominent inflammation (see reviews by French-Constant and Hemmer).

Nevertheless, most immunologists currently subscribe to the notion that MS is mediated by a T-cell sensitization to myelin. This idea is supported by numerous lines of evidence including the observation that T cells initiate the lesions of experimental allergic encephalomyelitis (EAE), which is assumed to be an animal model of MS, as suggested by Adams. Although the entry of autoreactive T cells into the CNS results in a perivascular inflammatory reaction, its relationship to MS is unclear. Conceivably, intense T-cell stimulation is in itself sufficient to induce demyelination, but it is also possible that the primary target of the immune reaction is the myelin sheath or some component thereof and that the T-cell infiltration is the result of the demyelination. Other investigators believe that an additional insult is required, as illustrated by the EAE animal model, in which myelin alone is not a sufficient factor but always requires an adjuvant immune stimulus. EAE is clearly an imperfect model; it is not a naturally occurring disease but one in which a demyelination of the CNS is induced in susceptible animals in a single episode by autologous myelin antigens. The
inducing antigen in EAE is known, whereas the putative antigen in MS is not.

Also incorporated into most theories of the immune pathogenesis is an alteration of the blood-brain barrier, represented by adhesion of lymphocytes to endothelial cells. Whether this is an active interaction or a passive event triggered by antigenic attraction is not clear; nonetheless, these cell-vascular interactions have been incorporated into pathogenic theories and is the basis of newer treatments for MS.

As matters now stand, the focus of attention is on the pathogenic role of specific subsets of T lymphocytes, which regulate humoral immune responses either as potentialtiators (T-helper cells) or as inhibitors (T-suppressor cells) of immunoglobulin production by the B lymphocytes. So-called helper (CD41) T cells are found in abundance within MS plaques and surrounding venules (peri-vascular cuffing). It has been demonstrated that T-cell receptors respond to antigens presented by (major histocompatibility complex, or MHC) class II molecules on macrophages and astrocytes. This interaction is thought to stimulate T-cell proliferation and a cascade of related cellular events, including the activation of B cells and macrophages and the secretion of cytokines (one of which is IFN-β and another IFN-γ; see further on). These cellular events are accompanied by a breakdown of the blood-brain barrier and, if sufficiently intense, by destruction of myelin (see review by French-Constant). A reduction in T cells, both helper and suppressor subsets, or an increase in the ratio of helper-suppressor cells, may precede an acute attack and appears to be associated with increasing disability in patients with MS. Always in the background is the element of genetic susceptibility, presumably making certain individuals prone to these immunologic events.

The foregoing data notwithstanding, it must be added that the immune mechanisms in MS are not fully specified and the autoimmune hypothesis is not beyond challenge. It is noteworthy that the prevalence of other diseases of presumed autoimmune origin is no higher in MS patients than in the general population (De Keyser). Moreover, the course of MS has been altered only inconsistently by the administration of any of the nonspecific immunosuppressive therapies (Goodkin et al, 1992).

Also worthy of comment is the relatively ineffective remyelination of the MS plaque. When remyelination of denuded axons occurs, thinly myelinated fibers are produced, creating areas of so-called shadow plaques. Histologic evidence suggests that some of the oligodendrocytes are destroyed in areas of active demyelination but also that some of the remaining ones have little ability to proliferate. Instead, there is an influx of oligodendroglial precursor cells, which mature into oligodendrocytes and provide the remaining axons with new myelin. Probably the astrocytic hyperplasia in regions of damage and the persistent inflammatory response account for some of the inadequacy of the reparative process (see Prineas et al).

**Physiologic Effects of Demyelination**

The main physiologic effect of demyelination is to impede saltatory electrical conduction of nerve impulses from one node of Ranvier, where sodium channels are concentrated, to the next node. The resulting failure of electrical transmission is thought to underlie most of the abnormalities of function resulting from demyelinating diseases of both the central and peripheral nerves. As an example, the delay in electrical conduction in the optic nerve (found by using pattern-shifting visual stimuli in MS patients) raises a number of points about the pathophysiology of demyelination. When the demyelinating process is acute and reversible within a few days, the block in nerve fiber conduction is obviously physiologic rather than pathologic; in such a brief period, recovery is unlikely to have been due to remyelination. Probably recovery is due to subsidence of the edema and acute inflammatory changes in and around the lesion. Remyelination probably does occur, as described above, but it is a slower process and partial at best, and its functional effects in the CNS are possibly expressed as a slowing of nerve conduction, which, if present in an eye with normal vision, may account for the reduction in flicker fusion and in the perception of multiple visual stimuli (Halliday and McDonald). It also explains one of the classic symptoms of optic neuritis—a reduction in the intensity (desaturation) of the color red. It is clear, however, that many of the plaques visualized on MRI are unaccompanied by corresponding symptoms; in some cases, there is no electrophysiologic abnormality as tested with evoked responses. Either there has been complete remyelination in these plaques, sufficient to support clinical functioning, or, in the acute stage, the plaque may represent edema rather than demyelination.

Another classic feature of MS is the temporary induction, by heat or exercise, of symptoms such as unilateral visual blurring (the Uthloff phenomenon) or tingling and weakness of a limb (the basis of the hot-tub test used in previous years). This has been shown experimentally to represent an extreme sensitivity of conduction in demyelinated nerve fibers to an elevation in temperature. A rise of only 0.5°C (0.9°F) can block electrical transmission in thinly myelinated or demyelinated fibers. Likewise, hyperventilation slows conduction of the visual evoked response, an effect that is rarely perceived by the patient. The remarkable sensitivity of demyelinated and remyelinated regions to subtle metabolic and environmental changes provides an explanation for the rapid onset of symptoms in some patients and the apparent fluctuations of MS that show no laboratory evidence of active inflammatory changes in the CNS. Smoking, fatigue, hyperventilation, and a rise in environmental temperature are all capable of briefly worsening neurologic functioning and are easily confused with relapses of disease.

**Precipitating Factors**

A variety of events occurring immediately before the initial symptoms or exacerbations of MS have been invoked as precipitating factors. The most common are infection, trauma, and pregnancy. However, in our view, none of these has been convincingly related to an increased risk of new attacks of MS, and there are no adequately controlled studies that would contradict this view. Nonetheless, we have had experience with several patients who regularly had acute exacerbations of MS following each outbreak of labial genital herpes. The incidence of respiratory or gastrointestinal viral infections that precede the onset or exacerbations of the disease varies greatly in different series, from 5 to 50 percent. The swine influenza vaccine, which was given to 45 million persons in the United States in late 1976, caused a slight increase in the incidence of Guillain-Barré disease but not of MS (Kurland et al), and more recent surveys of immunization programs, such as the one by Confavreux and colleagues (2001), confirm this.

The possible role of trauma in precipitating MS is more difficult to assess. McAlpine and Compston found that the incidence of trauma within a 3-month period preceding the onset of MS was slightly greater than in a random control group of hospital patients.
Furthermore, there appeared to be a relationship between the site of the injury and the site of initial symptoms, particularly in patients who developed symptoms within a week of injury. We do not find this evidence convincing. Other forms of trauma (including lumbar puncture and general surgical procedures) that occur after the onset of the neurologic disorder have not been shown to have an adverse effect on the course of the illness. Matthews, who has extensive personal experience with survivors of penetrating head wounds, did not find a single instance of MS among them. One of the most meaningful prospective studies of the relation of physical injury to MS is that of Sibley and colleagues, who followed 170 MS patients and 134 controls for an average of 5 years, during which they recorded all (1407) instances of trauma and measured their effects on exacerbation rate and progression of the disease. With the possible exception of a case or two of electrical injury, there was no significant correlation between traumatic episodes and exacerbations.

Certain other epidemiologic data have a bearing on this subject. There are, in the United States, 250,000 to 350,000 cases of physician-diagnosed MS (Anderson et al). Also, a study from the National Center for Health Statistics has determined that trauma sufficiently severe to be recalled at a periodic health examination occurs in one-third of the population of the United States (some 83 million persons) each year. Moreover, MS patients suffer physical injuries two or three times more often than normal persons (Sibley et al). In light of these data, it is perhaps not surprising that a traumatic event and an exacerbation should sometimes coincide, quite by chance.

**Clinical Manifestations**

The conventional view of MS as a disease that strikes young people at a time when they are enjoying perfect health is not always accurate. In some patients, the history discloses that fatigue, lack of energy, weight loss, and vague muscle and joint pains had been present for several weeks or months before the onset of neurologic symptoms. Nor is it generally appreciated that the neurologic disorder may have an acute, almost apoplectic onset. In fact, McAlpine and coworkers (1972), who analyzed the mode of onset in 219 patients, found that in about 20 percent the neurologic symptoms were fully developed in a matter of minutes, and, in a similar number, in a matter of hours. In about 30 percent the symptoms evolved more slowly, over a period of a day or several days, and in another 20 percent more slowly still, over several weeks to months. In the remaining 10 percent the symptoms had an insidious onset and slow, steady, or intermittent progression over months and years. The classic relapsing-remitting pattern of disease is more likely to appear in patients who are less than 40 years of age. The inflammatory process of MS affects no organ system other than the CNS.

**Early Symptoms and Signs** Weakness or numbness, sometimes both, in one or more limbs is the initial symptom in about half the patients. Symptoms of tingling of the extremities and tight band-like sensations around the trunk or limbs are commonly associated and are probably the result of involvement of the posterior columns of the spinal cord. The symptoms generally appear over a period of hours or days, at times being so trifling that they are ignored, and less often, coming on so acutely and prominently as to bring the patient urgently to the doctor. The resulting clinical syndromes vary from a mere dragging or poor control of one or both legs to a spastic or ataxic paraparesis. The tendon reflexes are retained and later become hyperactive with extensor plantar reflexes; disappearance of the abdominal reflexes and varying degrees of deep and superficial sensory loss may be associated. It is a useful adage that the patient with MS presents with symptoms in one leg but with signs in both; the patient will complain of weakness, incoordination, or numbness and tingling in one lower limb and prove to have bilateral Babinski signs and other evidence of bilateral corticospinal and posterior column disease.

Flexion of the neck may induce a tingling, electric-like feeling down the shoulders and back and, less commonly, down the anterior thighs. This phenomenon is known as a Lhermitte sign, although it is more a symptom than a sign and was originally described by Babinski in a case of cervical cord trauma. Lhermitte’s contribution was to draw attention to the frequent occurrence of this phenomenon in MS. It is attributable to an increased sensitivity of demyelinated axons to the stretch or pressure on the spinal cord induced by neck flexion.

There are, in addition, several syndromes that are typical of multiple sclerosis and may be the initial manifestations. These common modes of onset are: (1) optic neuritis, (2) transverse myelitis, (3) cerebellar ataxia, and (4) various brainstem syndromes (vertigo, facial pain or numbness, dysarthria, diplopia). These are often features of the established disease as well. When they represent the initial phases of the illness, they may pose diagnostic questions, since they also certainly occur with numerous diseases other than MS.

**Optic Neuritis** (See also page 213) In about 25 percent of all MS patients (and in a larger proportion of children), the initial manifestation is an episode of optic neuritis. It will be recalled that the optic nerve is in fact a tract of the brain, and involvement of the optic nerves is therefore consistent with the rule that lesions of MS are confined to the CNS. Characteristically, over a period of several days, there is partial or total loss of vision in one eye. Many patients, for a day or two before the visual loss, experience pain within the orbit, worsened by eye movement or palpation of the globe. Rarely, the visual loss is steadily progressive for several weeks, mimicking a compressive lesion or intrinsic tumor of the optic nerve (Ormerod and McDonald). Usually a scotoma involving the macular area and blind spot (ceccocentral) can be demonstrated, but a wide variety of other field defects may occur, rarely even hemianopic involvement (sometimes homonymous). In some patients, both optic nerves are involved, either simultaneously or, more commonly, within a few days or weeks of one another, and at least 1 in 8 patients will have repeated attacks. Serial examinations may disclose evidence of swelling or edema of the optic nerve head (papillitis) in about half the patients. The occurrence of papillitis depends on the proximity of the demyelinating lesion to the nerve head. As emphasized in Chap. 13, papillitis can be distinguished from the papilledema of increased intracranial pressure by the severe and acute visual loss that accompanies only the former. Matthew, who has extensive personal experience with survivors of penetrating head wounds, did not find a single instance of MS among them. One of the most meaningful prospective studies of the relation of physical injury to MS is that of Sibley and colleagues, who followed 170 MS patients and 134 controls for an average of 5 years, during which they recorded all (1407) instances of trauma and measured their effects on exacerbation rate and progression of the disease. With the possible exception of a case or two of electrical injury, there was no significant correlation between traumatic episodes and exacerbations.

Certain other epidemiologic data have a bearing on this subject. There are, in the United States, 250,000 to 350,000 cases of physician-diagnosed MS (Anderson et al). Also, a study from the National Center for Health Statistics has determined that trauma sufficiently severe to be recalled at a periodic health examination occurs in one-third of the population of the United States (some 83 million persons) each year. Moreover, MS patients suffer physical injuries two or three times more often than normal persons (Sibley et al). In light of these data, it is perhaps not surprising that a traumatic event and an exacerbation should sometimes coincide, quite by chance.

**Clinical Manifestations**

The conventional view of MS as a disease that strikes young people at a time when they are enjoying perfect health is not always accurate. In some patients, the history discloses that fatigue, lack of energy, weight loss, and vague muscle and joint pains had been present for several weeks or months before the onset of neurologic symptoms. Nor is it generally appreciated that the neurologic disorder may have an acute, almost apoplectic onset. In fact, McAlpine and coworkers (1972), who analyzed the mode of onset in 219 patients, found that in about 20 percent the neurologic symptoms were fully developed in a matter of minutes, and, in a similar number, in a matter of hours. In about 30 percent the symptoms evolved more slowly, over a period of a day or several days, and in another 20 percent more slowly still, over several weeks to months. In the remaining 10 percent the symptoms had an insidious onset and slow, steady, or intermittent progression over months and years. The classic relapsing-remitting pattern of disease is more likely to appear in patients who are less than 40 years of age. The inflammatory process of MS affects no organ system other than the CNS.

**Early Symptoms and Signs** Weakness or numbness, sometimes both, in one or more limbs is the initial symptom in about half the patients. Symptoms of tingling of the extremities and tight band-like sensations around the trunk or limbs are commonly associated and are probably the result of involvement of the posterior columns of the spinal cord. The symptoms generally appear over a period of hours or days, at times being so trifling that they are ignored, and less often, coming on so acutely and prominently as to bring the patient urgently to the doctor. The resulting clinical syndromes vary from a mere dragging or poor control of one or both legs to a spastic or ataxic paraparesis. The tendon reflexes are retained and later become hyperactive with extensor plantar reflexes; disappearance of the abdominal reflexes and varying degrees of deep and superficial sensory loss may be associated. It is a useful adage that the patient with MS presents with symptoms in one leg but with signs in both; the patient will complain of weakness, incoordination, or numbness and tingling in one lower limb and prove to have bilateral Babinski signs and other evidence of bilateral corticospinal and posterior column disease.

Flexion of the neck may induce a tingling, electric-like feeling down the shoulders and back and, less commonly, down the anterior thighs. This phenomenon is known as a Lhermitte sign, although it is more a symptom than a sign and was originally described by Babinski in a case of cervical cord trauma. Lhermitte’s contribution was to draw attention to the frequent occurrence of this phenomenon in MS. It is attributable to an increased sensitivity of demyelinated axons to the stretch or pressure on the spinal cord induced by neck flexion.

There are, in addition, several syndromes that are typical of multiple sclerosis and may be the initial manifestations. These common modes of onset are: (1) optic neuritis, (2) transverse myelitis, (3) cerebellar ataxia, and (4) various brainstem syndromes (vertigo, facial pain or numbness, dysarthria, diplopia). These are often features of the established disease as well. When they represent the initial phases of the illness, they may pose diagnostic questions, since they also certainly occur with numerous diseases other than MS.
but the pupil is said never to be dilated in ambient light. If the optic neuritis is unilateral, the consensual light reflex from the normal eye is retained. (Demyelination of the third nerve in its brainstem course, however, may be associated with a fixed enlargement of the pupil.)

As noted in Chap. 13, about half of patients with optic neuritis recover completely, and most of the remaining ones improve significantly, even those who present initially with profound visual loss and, later, pallor of the optic disc (Slamovits et al). Any pain in the globe is short-lived and persistent pain should prompt an evaluation for local disease. In a cohort of 397 patients enrolled in the Optic Neuritis Treatment Trial and examined 5 years after the initial attack of optic neuritis, visual acuity had returned to 20/25 or better in 87 percent of patients and to 20/40 or better in 94 percent—even if there had been a recurrence of optic neuritis during the 5-year period. Moreover, the mode of treatment did not appear to influence the outcome. Dyschromatopsia, generally taking the form of a perceived desaturation of colors, frequently persists. When improvement occurs, it usually begins within 2 weeks of onset, as is true of most acute manifestations of MS, perhaps sooner with corticosteroid treatment. Once improvement in neurologic function begins, it may continue for several months.

The main point to be made here is that one-half or more of adult patients who present with optic neuritis will eventually develop other signs of MS. The prospective investigation of Rizzo and Lessell showed that MS developed in 74 percent of women and 34 percent of men by the 15th year after onset of visual loss; similar results were reported by the Optic Neuritis Study Group (Beck and associates 2003). The risk is much lower if the initial attack of optic neuritis occurs in childhood [26 percent developed after 40 years of follow-up; Lucchini et al (1997)]; this suggests that some instances of the childhood disease may be of a different type, perhaps viral or postinfectious. Of more practical value is the observation, in the later study by Beck and colleagues, that the risk is also considerably lower (22 percent at 10 years) if the cranial MRI fails to reveal demyelinating lesions. The longer the period of observation and the greater the care given to detection of mild cases, the greater the proportion of patients who are found to develop signs of MS; however, most do so within 5 years of the original attack (Ebers, Hely et al). In fact, in many patients with clinically isolated optic neuritis, MRI has disclosed lesions of the cerebral white matter—suggesting that dissemination, albeit asymptomatic, had already occurred and thereby establishing the diagnosis of MS (Jacobs et al, Ormerod et al). The Optic Neuritis Study Group has made the point, well known to neurologists, that the recurrence of optic neuritis greatly increases the chances of developing MS.

It is unclear whether optic neuritis that occurs alone and is not followed by other evidence of demyelinating disease is simply a restricted form of MS or a manifestation of some other disease process, such as postinfectious encephalomyelitis. By far the most common pathologic basis for optic neuritis is demyelinative disease, though it is known that a vascular lesion or compression of an optic nerve by a tumor or mucocele may cause a central or cecocentral scotoma that is indistinguishable from the defect of optic neuritis. Also, there may exist a special form of chronic relapsing optic neuritis that is due to an undefined granulomatous process such as sarcoid and not to MS, as suggested by Kidd and colleagues. Spinal cord lesions have developed months or years later in almost all such cases under our care.

Uveitis and sheathing of the retinal veins are other ophthalmic disorders that occur with higher than expected incidence in patients with MS. The retinal vascular sheathing is due to T-cell infiltration, identical to that in typical plaques, but this is an anomalous finding, since the retina usually contains no myelinated fibers (Lightman et al).

The treatment of optic neuritis is discussed further on.

Acute Myelitis (Transverse Myelitis) This is the common designation for an acutely evolving inflammatory-demyelinative lesion of the spinal cord, which proves in many but not all instances to be an expression of MS. In this sense the myelitic lesion is analogous to that of optic neuritis. The term transverse in relation to the myelitis is somewhat imprecise, implying that all of the elements in the cord are involved in the transverse plane, usually over a short vertical extent. Instead, in MS, the spinal cord signs are asymmetrical and incomplete and involve only a part of the long ascending and descending tracts, i.e., paraplegia and complete sensory loss are unusual.

Clinically, the illness is characterized by a rapidly evolving (several hours or days) symmetrical or asymmetrical paraparesis or paraplegia, ascending paresthesias, loss of deep sensibility in the feet, a sensory level on the trunk, sphincteric dysfunction, and bilateral Babinski signs. The CSF shows a modest number of lymphocytes and increase in total protein but both may be normal early in the illness. As many as one-third of patients report an infectious illness in the weeks preceding the onset of neurologic symptoms, in which case a monophasic postinfectious demyelinating disease rather than MS is the likely cause of the myelitis. The MRI usually shows indications of focal demyelination in the spinal cord at the appropriate level and there may be enhancement with gadolinium infusion, but neither of these findings is invariable. The lesions, as shown in Fig. 36-1 (right panel), are almost indistinguishable from those of postinfectious myelitis. In those instances associated with existing MS, even if not previously symptomatic, MRI of the cerebral hemispheres will show lesions consistent with demyelination; the absence of such lesions, however, does not assure that the illness is monophasic and will not later turn out to be MS.

We have found that fewer than half the patients have evidence of an asymptomatic demyelinating lesion elsewhere in the nervous system or develop clinical evidence of dissemination within 5 years of the initial attack of acute myelitis (Ropper and Poskanzer). Not entirely in accord with our experience is the analysis of subgroups in a trial of interferon therapy conducted by Beck and colleagues (2002), in which the cumulative probability of developing MS after 2 years was similar after either optic neuritis or transverse myelitis. Our sense has been that acute transverse myelitis is somewhat less often an initial expression of MS than is optic neuritis.

A special problem is presented by patients with recurrent myelitis at one level of the spinal cord but in whom no other signs of demyelinative disease can be found by careful clinical examination or MRI. Some of them may even have oligoclonal bands in the CSF, which are commonly associated with MS (see further on). Enough cases of this limited nature have come to our attention to permit the conclusion that there is a recurrent form of spinal cord MS in which cerebral dissemination is infrequent (Tippett et al). It should be mentioned that isolated recurrent myelitis or myelopathy occurs also with lupus erythematosus, sarcoid, Sjögren syndrome, mixed connective tissue disease, and the antiphospholipid antibody syndrome or in the presence of other autoantibodies, as well as with dural and cord vascular fistulas and arteriovenous malformations. An analogous situation pertains in respect to some instances
of optic neuritis—repeated attacks that remain confined to the optic nerve.

Other aspects of transverse myelitis are discussed in Chap. 44, “Diseases of the Spinal Cord,” and under “Acute Disseminated Encephalomyelitis” later in this chapter.

Other Patterns of Multiple Sclerosis (See also “Variants of MS,” page 780) Like the modes of onset cited above, other early manifestations of MS, in descending order of frequency, are unsteadiness in walking, brainstem symptoms (diplopia, vertigo, vomiting, etc.), paresthesias or numbness of an entire arm or leg, facial pain often simulating tic doloreux, and disorders of micturition. Vertigo of central type is also a frequent initial sign of MS, but it more often appears in established cases. Discrete manifestations—such as hemiplegia, trigeminal neuralgia or other pain syndromes, facial paralysis, deafness, or seizures—occur in a small proportion of cases. Most often the disease presents with more than one of the aforementioned symptoms almost simultaneously or in rapid succession. Another relatively isolated syndrome of note, occurring mainly in older women, is a slowly progressive cervical myelopathy with weakness and ataxia. This is particularly difficult to differentiate from cervical spondylosis.

Not infrequently a prominent feature of the disease is nystagmus and ataxia, with or without weakness and spasticity of the limbs—a syndrome that reflects involvement of the cerebellar and corticospinal tracts. Ataxia of cerebellar type can be recognized by scanning speech, rhythmic instability of the head and trunk, intention tremor of the arms and legs, and incoordination of voluntary movements and gait, as described in Chap. 5. The combination of nystagmus, scanning speech, and intention tremor is known as the Charcot’s triad. But while this group of symptoms is often seen in the advanced stages of the disease, most neurologists would agree that it is not a common mode of presentation. The most severe forms of cerebellar ataxia, in which the slightest attempt to move the trunk or limbs precipitates a violent and uncontrollable ataxic tremor, are observed among patients with long-standing MS. The responsible lesion probably lies in the tegmentum of the midbrain and involves the dentatorubrothalamic tracts and adjacent structures. Cerebellar ataxia may be combined with sensory ataxia, owing to involvement of the posterior columns of the spinal cord or medial lemnisci of the brainstem. In most cases of this type the signs of spinal cord involvement ultimately predominate; in others, the cerebellar signs are more prominent.

Diplopia is another common presenting complaint. It is due most often to involvement of the medial longitudinal fasciculi, producing an internuclear ophthalmo palsia (see page 236). The signs are characterized by paresis of the medial rectus on attempted lateral gaze, with a coarse nystagmus in the abducting eye; in MS, this abnormality is usually bilateral (unlike small pontine infarcts, which cause a unilateral internuclear ophthalmoplegia). As a corollary, the presence of bilateral internuclear ophthalmoplegia in a young adult is virtually diagnostic of MS. Occasionally, internuclear ophthalmoplegia in one direction is combined with a horizontal gaze paresis in the other, although this “one-and-a-half syndrome” is more typical of brainstem stroke (see also page 236). Other palsies of gaze (due to interruption of supranuclear connections) or palsies of individual ocular muscles (due to involvement of the ocular motor nerves in their intramedullary course) also occur, but less frequently. Additional manifestations of brainstem involvement include myokymia or paralysis of facial muscles, deafness, tinnitus, unformed auditory hallucinations (because of involvement of cochlear connections), vertigo—as noted above, vomiting (vestibular connections), and rarely stupor and coma. The occurrence of transient facial hypesthesia or anesthesia or of trigeminal neuralgia in a young adult should always suggest the diagnosis of MS implicating the intramedullary fibers of the fifth cranial nerve.

Dull, aching, but otherwise nondescript pain in the low back is a common complaint, but its relation to the lesions of MS is uncertain. Infrequently, there is sharp, burning, poorly localized, or lancinating-radicular pain, localized to a limb or discrete part of the trunk. Nevertheless, these types of pains, presumably caused by demyelinating foci involving the dorsal root entry zones, have a few times been the presenting feature of the disease or have appeared at a later time in established cases (see Ramirez-Lassepas et al for a discussion of pain in MS).

Symptoms and Signs in the Established Stage of the Disease

When the diagnosis of MS has become virtually certain, a number of clinical syndromes are observed to occur with regularity. Approximately one-half of the patients will manifest a clinical picture of mixed or generalized type with signs pointing to involvement of the optic nerves, brainstem, cerebellum, and spinal cord—specifically signs relating to the posterior columns and corticospinal tracts. Another 30 to 40 percent will exhibit only varying degrees of spastic ataxia and deep sensory changes in the extremities, i.e., essentially a spinal form of the disease. In either case, an asymmetrical spastic paraparesis with some degree of impaired joint position and vibration sense in the legs is probably the most common manifestation of progressive MS. A predominantly cerebellar or pontobulbar cerebellar form will be noted in only about 5 percent of cases. Thus the mixed and spinal forms together have made up at least 80 percent of our clinical material.

It has become evident from some studies that some degree of cognitive decline is present in perhaps one-half of patients with long-standing MS. The process is characterized by reduced attention, diminished processing speed and executive skills, and memory decline, while language skills and other intellectual functions are preserved—features that have been subsumed under “subcortical dementia,” as discussed in Chap. 21. Other mental disturbances—such as a loss of retentive memory, a global dementia, or a confusional-psychogetic state—are also said to occur with some regularity in the advanced stages of the disease, but we have found this degree of deterioration to be exceptional. The decline in cognitive functions correlates with quantifiable MRI measurements, particularly loss of white matter volume, thinning of the corpus callosum, and brain atrophy (reviewed by Bobholz and Rao).

Traditional teaching has probably overemphasized the frequency of euphoria, a pathologic cheerfulness or elation that seems inappropriate in the face of the obvious neurologic deficit. (Charcot spoke of this phenomenon as “stupid indifference” and Vulpian as “morbid optimism.”) Some patients do show this mental abnormality, always in association with other signs of cerebral impairment. In some instances it is manifestly a part of the syndrome of pseudobulbar palsy. A much larger number of patients, however, are depressed, irritable, and short-tempered as a reaction to the disabling features of the disease; the incidence of depression is estimated to be as high as 25 to 40 percent in some series. Dalos and coworkers, in comparing MS patients with a group of traumatic paraplegics, found a significantly higher incidence of emotional disturbance in the former group, especially during periods of relapse. Other mental disturbances—such as a loss of retentive mem-
ory, a global dementia with deteriorated executive function, or a confusional-psychotic state—also occur in the advanced stages of the disease. The cognitive impairment is more in keeping with what has been ascribed to “subcortical dementia” (page 372).

Symptoms of bladder dysfunction—including hesitancy, urgency, frequency, and incontinence—occur commonly with spinal cord involvement. Urinary retention, due to affection of sacral segments, is less frequent (Fig. 26-5). In males, these symptoms are often associated with impotence, a symptom that the patient may not report unless specifically questioned in this regard.

Abrupt attacks of neurologic deficit, lasting a few seconds or minutes and sometimes recurring many times daily, are a relatively infrequent but well-recognized feature of MS (see Osterman and Westerbey). Usually the attacks occur during the relapsing and remitting phase of the illness, rarely as an initial manifestation. These clinical phenomena are referable to any part of the CNS but tend to be stereotyped in an individual patient. The most common phenomena are dysarthria and ataxia, paroxysmal pain and dysesthesia in a limb, flashing lights, paroxysmal itching, or tonic seizures, taking the form of flexion (dystonic) spasm of the hand, wrist, and elbow with extension of the lower limb. The paroxysmal symptoms, particularly the tonic spasms, may be triggered by sensory stimuli or can be elicited by hyperventilation. On a few occasions we have seen dystonic hand and arm spasms as the first symptoms; an acute plaque was detected in the opposite internal capsule. In advanced cases, the spasms may involve all four limbs and even a degree of opisthotonus. The cause of paroxysmal phenomena is uncertain. They have been attributed by Halliday and McDonald to ephaptic transmission (“cross-talk”) between adjacent demyelinated axons within a lesion. Carbamazepine is usually effective in controlling such attacks.

These transitory symptoms appear suddenly, may recur frequently for several days or weeks, sometimes longer, and then remit completely, i.e., they exhibit the temporal profile of a relapse or an exacerbation. It is sometimes difficult to determine whether they represent an exacerbation or a new lesion. Years ago, Thygesen pointed out, in an analysis of 105 exacerbations in 60 patients, that there were new symptoms in only 19 percent; in the remainder there was only a recurrence of old symptoms. Another problem is that the original lesion may have been asymptomatic. This is most obviously reflected in the many patients who are found to have impaired visual evoked responses but have never had symptomatic visual changes. Thus, new symptoms and signs may be manifestations of previously formed but asymptomatic plaques. However, the observations of Prineas and Connell indicate that symptoms and signs may progress without the appearance of new plaques. These and other factors need to be taken into consideration in evaluating the clinical course of the illness and the effects of a therapeutic program (see Poser).

Unusually severe fatigue is another peculiar symptom of MS; it is often transient and more likely to occur when there is fever or other evidence of disease activity, but it can be a persistent complaint and a source of considerable distress. Depression may play a role in these recalcitrant cases, although the response to pharmacologic agents suggests that these two aspects of the disease are dissociable. Thus, antidepressants often do not improve fatigue, while drugs that alleviate fatigue, such as modafinil and amantadine, do not function as antidepressants.

A number of other interesting manifestations of MS have come to our attention over the years and have given rise to difficulties in diagnosis. The occurrence of typical tic douloureux in young patients has already been mentioned; only their young age and the bilaterality of the pain in some of them raised the suspicion of MS, confirmed later by sensory loss in the face and other neurologic signs. It is notable, however, that facial palsy along the lines of Bell’s palsy is almost never a sign of MS. Brachial, thoracic, or lumbosacral pain consisting mainly of thermal and algic dysesthesias, was a source of puzzlement in several other patients until additional lesions developed. Other types of pain in MS have been addressed earlier. In two of our cases, the relatively acute occurrence of a right hemiplegia and aphasia first raised the probability of a cerebrovascular lesion; in still others, a more slowly evolving hemiplegia had led to an initial diagnosis of a cerebral glioma. The dystonic and paroxysmal symptoms are mentioned above; they do not typically bring the diagnosis of MS to mind.

Approximately 3 percent of patients reportedly have focal seizures, but it should be emphasized that this is usually in relation to an obvious cerebral lesion and advanced disease of many years duration. Seizures at an early stage of illness are almost always attributable to previous head injury, idiopathic epilepsy, or as in a recent case, withdrawal of sleep medication. Several times we have seen coma during relapse of MS, and in each instance it continued to death. In one case it occurred in a 64-year-old woman who had two previous episodes of nondoning spinal MS at 30 and 44 years of age. A confusional psychosis with drowsiness was the initial syndrome in another patient whom we saw later with a relapse involving the cerebellum and spinal cord. Another unusual syndrome is one of slow intellectual decline with slight cerebellar ataxia. A 10-year, slowly progressive cerebellar ataxia in an adolescent girl was perplexing until she later developed internuclear ophthalmoplegia. A rapid onset of ascending paralysis of legs, bladder and bowel, and trunk with severe pain in sacral parts, areflexia, and a mononuclear pleocytosis of 1600 cells per cubic millimeter occurred in another of our patients and lasted 2 years before she began to walk again; earlier she had had diplonia and retrobulbar neuritis. Cases similar to these develop a necrotic myelopathy that is similar to Devic disease and there is little recovery.

As mentioned in the chapter on spinal cord disease, some instances of MS in late adult life take the form of a slowly progressive cervical myelopathy. There is also certainly a form of spinal MS without cerebral involvement, as noted further on.

Seemingly more frequently in recent years, we have observed patients whose illness satisfied all the clinical criteria for the diagnosis of MS except for the onset of symptoms in the sixth or seventh decade. Presumably we were witnessing the late deteriorative phase of the illness, earlier symptoms having been forgotten or having never been recognized. Contrariwise, in our pathologic material (and increasingly with the ubiquitous use of MRI scans), we have several times found a few typical lesions of MS to which the clinical records make no reference.

**Variants of Multiple Sclerosis**

Several variants of MS merit more extended discussion. They are acute MS, neuromyelitis optica, acquired Schilder disease, and the conjunction of MS and polyneuropathy. The chronic progressive variety of MS presents special problems that are addressed in a later section on “Clinical Course and Prognosis.”

**Acute Multiple Sclerosis** Rarely, MS takes a rapidly progressive and highly malignant form; Marburg’s name has been attached to this variant. A combination of cerebral, brainstem, and spinal man-
Neuromyelitis Optica (Devic Disease, Necrotic Myelopathy; See also Chap. 46) Here, there is a simultaneous or successive and usually severe involvement of optic nerves and spinal cord. The combination was remarked upon by Clifford Albutt in 1870, and Gault (1894), stimulated by his teacher Devic, devoted his thesis to the subject. Devic subsequently endeavored to crystallize medical thought about a condition that has come to be known as neuromyelitis optica. Its principal features are the acute to subacute onset of blindness in one or both eyes, preceded or followed within days or weeks by a severe transverse or ascending myelitis (Mandler et al). The spinal cord lesions in cases of neuromyelitis optica are often necrotizing rather than purely demyelinative in type, leading eventually to cavitation; as would be expected, the clinical effects are more likely to be permanent than those of demyelination. A few of the patients have been children; in a number of instances, they suffered only a single episode of neurologic illness.

Although it is true that cases corresponding to this prototype are seen on occasion in every large medical center and at all age periods, the isolation of such an entity on clinical grounds alone has been unsatisfactory. At least half of our patients have proved by subsequent clinical developments, and in a few instances by autopsy, to have chronic relapsing MS. In one notable example, where hemiplegia and aphasia were followed within 2 weeks by a necrotizing myelitis from which there was no recovery, the patient later developed typical attacks of MS, including retrobulbar neuritis. At autopsy, more than 15 cm of the spinal cord had been destroyed, reducing it to a collapsed membranous tube. Elsewhere in the brain and cord the lesions were typically demyelinative.

One might conclude from cases such as these that neuromyelitis optica is but a variant form of MS (or some other type of demyelinative disease). Many cases of neuromyelitis optica, however, stand apart from MS by virtue of a number of distinctive clinical and pathologic features—namely, a failure to develop brainstem, cerebellar, or cerebral demyelinative lesions and normality of the cerebral white matter on MRI, even after several years of illness; almost uniform absence of oligoclonal bands and other abnormalities of IgG in the spinal fluid; and finally, the necrotizing and cavitory nature of the spinal cord lesion, affecting white and gray matter alike with prominent thickening of vessels but without inflammatory infiltrates. On the basis of these differences, Mandler and O’Riordan and their colleagues and others have favored the separation of Devic disease from MS. For reasons mentioned above, we are uncertain that the distinction is quite so clear or perhaps there are two types of disease, only one of which is allied with MS. Recently, evidence of antibody binding, complement activation, and eosinophilic infiltration has led to the conclusion that the Devic process is a humoral disease, in contrast to the cellular mechanism that has been proposed for MS (see Lucchinetti et al, 2002). In support of this notion is the finding of a serum IgG antibody directed against capillaries in the brainstem and cerebellum. Lennon and colleagues have reported that this is a marker for neuromyelitis optica in half of the cases and is absent in MS. Insofar as the cause of neither MS nor Devic disease is known, uncertainties about the relationship of these diseases cannot be resolved with finality. It should also be noted that acute disseminated encephalomyelitis may occasionally present as a neuromyelitis optica syndrome.

There is in addition a progressive and saltatory subacute necrotic myelopathy without optic neuritis that shares all the myelopathic features of Devic disease but not the optic neuropathy and, in our view, probably represents the same entity (Katz and Ropper). In our clinics, such purely myelopathic cases outnumber those of Devic disease. The differential diagnosis here is broader and includes specifically arteriovenous malformation of the cord or dura and, of lesser resemblance, infarction or neoplasm of the cord. Also, a rare isolated vasculitis of the cord may cause a necrotic myelopathy; it is associated with an active CSF pleocytosis (Ropper et al). The cord in the cases we have studied was swollen on
MRI in the early stages, often with edema extending many segments above and below the area of primary disease, and later became atrophic. Up to 50 cells are typical in the CSF and the protein is elevated, but the spinal fluid may be normal during periods of clinical stability. Several of these cases have had positive IgG antibodies as tested in Weinshaker’s laboratory (see above), further supporting the notion that these cases are allied with Devic disease but leaving ambiguous the relationship of both entities to MS.

**Treatment** The treatment of neuromyelitis optica and of subacute necrotic myelopathy has been largely unsuccessful, most cases progressing despite aggressive therapy, including high-dose corticosteroids, plasma exchange, intravenous immunoglobulin, azathioprine, and cyclophosphamide. A study of several patients by Mandler and colleagues (1998) suggested that perhaps a combination of high-dose methylprednisolone and azathioprine led to clinical improvement; we cannot affirm this approach, but most other treatments have given poor results in our experience. Because some individuals respond (albeit infrequently) to them, it is appropriate to try one or more of these therapies in these cases.

**Diffuse Cerebral Sclerosis of Schilder**  
(Schilder Disease, Encephalitis Periaxialis Diffusa)  
Exceptionally the cerebrum is the site of massive demyelination, occurring in multiple foci or as a single large focus. Such cases are more frequent in childhood and adolescence than in adult life. Despite the undoubted occurrence of such cases, to call them “Schilder disease” is to refer to a clinical entity of ambiguous standing.

The term *diffuse sclerosis* was probably first used by Strumpell (1879) to describe the hard texture of the freshly removed brain of an alcoholic; later the term was applied to widespread cerebral gliosis of whatever cause. In 1912, Schilder described an instance of what he considered to be “diffuse sclerosis.” The case was that of a 14-year-old girl with progressive mental deterioration and signs of increased intracranial pressure, terminating fatally after 19 weeks. Postmortem examination disclosed large, well-demarcated areas of demyelination in the white matter of both cerebral hemispheres as well as a number of smaller demyelinating foci, resembling the common lesions of MS. Because of the similarities of the pathologic changes to those of MS (prominence of the inflammatory reaction and relative sparing of axons), Schilder called this disease *encephalitis periaxialis diffusa*, bringing it in line with *encephalitis periaxialis scleroticans*, a term that Marburg had used to describe a case of acute MS. Unfortunately, in subsequent publications, Schilder applied the same term to two other conditions of different type. One appears to have been a familial leukodystrophy (probably adrenoleukodystrophy) in a boy, and the other, quite unlike either of the first two cases, was suggestive of an infiltrative lymphoma. The last two reports seriously confused the subject, and for many years the terms *Schilder disease and diffuse sclerosis* were therefore indiscriminately attached to quite different conditions.

One group of diseases of the cerebral white matter, which can be readily culled from the overall category of diffuse sclerosis, is the leukodystrophies, including adrenoleukodystrophy of boys and young men, globoid-cell leukodystrophy of Krabbe, sudanophilic leukodystrophy, and metachromatic leukodystrophy—all of which may involve peripheral nerves as well as the CNS tissue. The leukodystrophies (discussed in detail in Chap. 37) are characterized clinically by progressive visual failure, mental deterioration, and spastic paralysis and pathologically by massive and more or less symmetrical destruction of the white matter of the cerebral hemispheres. In each of them there is a specific inherited biochemical defect in the metabolism of myelin proteolipids.

If one sets aside the hereditary metabolic leukodystrophies and other childhood disorders of cerebral white matter that were incorrectly included under the rubric of “Schilder disease” or “diffuse sclerosis,” there remains a characteristic group of cases that does indeed correspond to Schilder’s original case description. They are nonfamilial and are most frequently encountered in children or young adults. As with the case reported by Ellison and Barron, the disease may follow the course of MS, either steady and unremitting or punctuated by a series of episodes of rapid worsening. In rare instances the disease may become arrested for many years, or the patient may even improve for a time. Dementia, homonymous hemianopia, cerebral blindness and deafness, varying degrees of hemiplegia and quadriplegia, and pseudobulbar palsy are the usual clinical findings. Optic neuritis may occur before or after the cerebral symptoms. The CSF may show changes similar to those in chronic relapsing MS, but often there are no oligoclonal bands; instead, myelin basic protein is found in large quantity in the CSF. Death occurs in most patients within a few months or years, but some survive for a decade or longer. In the differential diagnosis, a diffuse cerebral neoplasm (gliomatosis or lymphoma), adrenoleukodystrophy, and progressive multifocal leukoencephalopathy (Chap. 33) are the main considerations.

The characteristic lesion in these cases is a large, sharply outlined, asymmetrical focus of myelin destruction often involving an entire lobe or cerebral hemisphere, typically with extension across the corpus callosum and involvement of the opposite hemisphere (Fig. 36-2). In some cases both hemispheres may be symmetrically involved. A careful examination of the optic nerves, brainstem, and spinal cord often discloses the typical discrete lesions of MS. Histologically, the large single focus as well as the smaller disseminated ones show the characteristic features of MS.

![Figure 36-2. Diffuse cerebral sclerosis (Schilder disease). MRI showing large asymmetrical foci of involvement of white matter in a 12-year-old boy 2 1/2 months after onset of symptoms. The clinical picture was one of rapidly worsening episodes of bilateral hemiplegia and hemianopia. (Reproduced by permission from Bisse JH, Cranial MRI, New York, McGraw-Hill, 1991.)](image-url)
Poser’s review of the literature in 1957 uncovered 105 cases that could be designated as the Schilder type of diffuse sclerosis in the original sense of the term. In 33 of these, the only lesions were the extensive areas of demyelination involving the centrum ovale; most of the patients in this group were children, and the disease had a tendency to take a subacute progressive course. In 72 patients, in addition to the large foci in the cerebral white matter, isolated demyelinating plaques were found in other parts of the central nervous system; the age of onset in this latter group was similar to that of chronic, relapsing MS. Frequently, the illness ran a protracted and remitting course. These findings were elaborated by Poser and colleagues in a subsequent (1986) review of this subject. It is apparent that diffuse cerebral sclerosis of this type must be closely related to MS and may indeed be a variant of it, as Schilder originally proposed.

The *concentric sclerosis of Balo* is probably a variety of Schilder disease, which it resembles in its clinical aspects and in the overall distribution of its lesions. The distinguishing feature is the occurrence of alternating bands of destruction and preservation of myelin in a series of concentric rings. The occurrence of lesions in this pattern suggests the centrifugal diffusion of some factor that is damaging to myelin. A similar pattern of lesions, although far less extensive, is seen in occasional cases of chronic relapsing MS.

**Multiple Sclerosis in Conjunction with Peripheral Neuropathy**

From time to time there have been patients with MS who also have a polyneuropathy or mononeuropathy multiplex. This relationship always invites speculation and controversy. The rarity of the combination suggests a purely coincidental occurrence, perhaps with another underlying disease as an explanation (e.g., Lyme disease, AIDS). Another view, expressed by Thomas and colleagues and by Mendell et al, is that an autoimmune demyelination has been incited in both spinal cord and peripheral nerve, the latter taking the form of a chronic inflammatory polyradiculoneuropathy. Of course, radicular and neuropathic symptoms, motor and/or sensory, can result from the involvement of myelinated fibers in the root entry zone of the cord or fibers of exit in the ventral white matter. And in the late stages of MS there is always the possibility of vitamin deficiency polyneuropathy or multiple pressure palsies. At the moment, we consider the two components to be different in origin.

**Laboratory Findings**

**Cerebrospinal Fluid**  In about one-third of all MS patients, particularly those with an acute onset or an exacerbation, there may be a slight to moderate mononuclear pleocytosis (usually in the range of 6 to 20 and in any case, less than 50 cells per cubic millimeter). In rapidly progressive cases of neuromyelitis optica (see above) and in certain instances of severe demyelinative disease of the brainstem, the total cell count may reach or exceed 100 and rarely 1000 cells per cubic millimeter; in the hyperacute cases, the greater proportion of these may be polymorphonuclear leukocytes. This pleocytosis may in fact be the only measure of activity of the disease.

It has been shown that the gamma globulin proteins in the CSF of patients with MS are synthesized in the CNS (Tourtellotte and Booe) and that they migrate in agarose electrophoresis as abnormal discrete populations, so-called *oligoclonal bands*. This is currently the most widely used CSF test for the confirmation of the diagnosis. Determination of the IgG index and testing for oligoclonal IgG bands is done in most commercial and hospital laboratories and will show several bands in the CSF in more than 90 percent of cases of MS. Such bands also appear in the CSF of patients with syphilis, Lyme, and subacute sclerosing panencephalitis—disorders, with perhaps the exception of the second one, that should not be difficult to distinguish from MS on clinical grounds. The demonstration of oligoclonal bands in the CSF and not in the blood is particularly helpful in confirming the diagnosis of MS, but they are not always found with the first attack or even in the later stages of the disease. The presence of such bands in a first attack of MS is predictive of chronic relapsing MS, according to Moulin and coworkers and others. Oligoclonal bands are usually reported as being present if there is more than one band; the meaning of a single band is not clear, and we have treated this result as a negative test. As already pointed out, some of the dramatic variants of MS such as necrotic myelopathy and Devic disease generally lack oligoclonal bands.

Also, in about 40 percent of patients, the total protein content of the CSF is increased. The increase is slight, however, and a concentration of more than 100 mg/dL is so unusual that the possibility of another diagnosis should be entertained. More importantly, the proportion of gamma globulin (essentially IgG) is increased (greater than 12 percent of the total protein) in about two-thirds of patients. Another less frequently used diagnostic measure is the IgG index, which is obtained by measuring albumin and gamma globulin in both the serum and CSF and using the following formula:

\[
\text{CSF IgG/serum IgG} = \frac{\text{CSF IgG}}{\text{serum IgG}}
\]

\[
\text{CSF alb/serum alb} = \frac{\text{CSF albumin}}{\text{serum albumin}}
\]

A ratio of more than 1.7 indicates the probability of MS.

It has also been shown, by the use of a sensitive radiomunoassay, that the CSF of many patients contains high concentrations of myelin basic protein (MBP) during acute exacerbations of MS and that these levels are lower or normal in slowly progressive MS and normal during remissions of the disease (Cohen et al). Other lesions that destroy myelin (e.g., infarction) can also increase the level of MBP in the spinal fluid. Thus the assay is not particularly useful as a diagnostic test and probably simply reflects the destruction of central myelin. The method is not simple but is available commercially.

When cells, total protein, gamma globulin, and oligoclonal bands are all taken into account, some abnormality of the spinal fluid will be found in the great majority of patients with MS. At present the measurement of gamma globulins as a fraction of total protein and oligoclonal bands in the CSF are the most reliable of the chemical tests for MS, particularly when the test is taken some interval after an acute exacerbation or during the chronic progressive phase of disease. We are not convinced that other, more complicated laboratory procedures, such as CSF measurements of globulin production or MBP, provide additional diagnostic sensitivity.

The results of Berger and colleagues, mentioned earlier in the discussion of pathogenesis, may in the future introduce into practice the measurement of serum antibodies against myelin basic protein and oligodendrocyte glycoprotein, as noted further on.

**Magnetic Resonance Imaging in Multiple Sclerosis**  It is now widely appreciated that MRI is the most helpful ancillary examination in the diagnosis of MS, by virtue of its ability to reveal asymptomatic plaques in the cerebrum, brainstem, optic nerves, and spinal cord (see Fig. 36-1). Most experience accords with that
of Stewart and coworkers, who found multifocal lesions in the cerebrum in 80 percent of their established cases. In a series of 114 patients with clinically definite MS, Ormerod and colleagues detected T2-intense periventricular MRI abnormalities in all but 2 patients and discrete cerebral white matter lesions in all but 12. With newer imaging sequences, the proportion with lesions is even higher, greater than 90 percent in some series. It is remarkable that even when there are a multitude of cerebral lesions, they tend to be asymptomatic; by contrast, spinal cord lesions are almost always symptomatic. Also, attention has been drawn by Bot and colleagues to lesions in the spinal cord that allow for diagnosis based on the identification of a second involved site in the nervous system. However, even in their series of 104 patients, only 3 had an abnormality in the cord and none in the cerebrum.

Several MRI features are characteristic of the chronic MS lesion; some of these are dependent on the field strength of the magnet and the ratio of T1 and T2 weighting. In general, chronic MS plaques are hyperintense (white) on T2-weighted images and even more strikingly obvious on FLAIR images (although we have seen the opposite pattern in some posterior fossa lesions). Lesions that have undergone some degree of cavitation, as happens only occasionally, are hypointense on T1-weighted images. Longitudinal analyses reveal a slow increase over time in the total burden of hypointense T1 images; in one study, these increased with the numbers of enhancing lesions in untreated patients (Simon).

The discrete cerebral lesions of MS do not always impart a specific MRI appearance; but the finding on T2-weighted images of several asymmetrical, well-demarcated lesions immediately adjacent to the ventricular surface usually denotes MS. Especially diagnostic are oval or linear regions of demyelination, oriented perpendicularly to the ventricular surface; they correspond to the radially oriented fiber bundles of the white matter and periventricular veins. When viewed in sagittal images, they extend outward from the corpus callosum in a fimbriated pattern and have been termed “Dawson fingers.” These areas may extend into the centrum semiovale and may reach the convolutonal white matter (Fig. 36-1). Even one highly characteristic lesion is sometimes enough to confirm the diagnosis in the proper clinical circumstances; multiple lesions are more convincing. The presence of such lesions in the corpus callosum is diagnostically useful, as this structure is spared in many other disorders.

Early in the evolution of an MS lesion there is disruption of the blood-brain barrier, presumably as a consequence of inflammation. The MRI correlate is enhancement following the administration of gadolinium. Although usually readily apparent, this aspect may be exposed only by administration of double or triple the usual dose of gadolinium. Gadolinium enhancement may last for 3 to 4 months following the development of the acute lesion. Otherwise, the signal characteristics of MS lesions are not obviously dependent on the age of the lesions.

In advanced cases of MS, the lesions become confluent, usually at the poles of the ventricles. The spectrum of these changes has been commented on by Berry and colleagues. Infrequently, a large acute lesion may have a mass effect and a ring-like contrast-enhancing border, resembling a glioblastoma or an infarct; the correct diagnosis may then be made only by biopsy. A series of focal tumor-like lesions of the brain, the demyelinating nature of which became evident only after biopsy, has been reported by Kepes. Serially performed MRIs can demonstrate the progress of the disease by the accumulation of increasing numbers of cerebral lesions; but even then they usually remain asymptomatic. As mentioned, lesions in the spinal cord that are detected by MRI are more likely to be symptomatic, but there are striking exceptions. As with other laboratory procedures, MRI changes assume maximal diagnostic significance when they are consistent with the clinical findings.

Increasingly, other aspects of the pathology of MS lesions have been delineated using MRI studies, such as the processes of plaque remyelination, axonal degeneration and brain atrophy. As assessed histologically in 36 brains with both autopsies and MRI studies, remyelinated foci were quite common and correlated well with persistent T2 hyperintensity; on the other hand, T1 hypointensity was inversely proportional to the degree of remyelination (Barkhof). Several studies have documented that slowly progressive brain atrophy, as gauged by volumetric MRI measurements, is a feature of long-standing MS. This is demonstrable both early and late in the disease and correlates loosely with disability. The basis for the atrophy is not fully defined. It probably reflects both the loss of glial cells and, importantly, wallerian degeneration and loss of axons triggered acutely by inflammation and more chronically by other neurodegenerative stimuli (Miller). In the investigation of brain atrophy in MS, volumetric studies have been supplemented by spectroscopic biochemical analyses; some studies have demonstrated a correlation between various measures of atrophy, levels of N-acetyl-aspartate (NAA, a marker of axons), and disability.

It should be stressed that foci of periventricular hyperintensity are observed with a variety of pathologic processes and even in normal persons, particularly older ones; in the older individuals, the periventricular changes are usually milder in degree, less dense, and smoother in outline than the lesions of MS.

**Evoked Potentials and Other Confirmatory Tests** When the clinical data point to only one lesion in the CNS, as often happens in the early stages of the disease or in the spinal form, a number of other sensitive physiologic and radiologic tests may establish the existence of additional asymptomatic lesions. These include visual, auditory, and somatosensory evoked responses and the less standardized and infrequently tested perceptual delay on visual stimulation; electro-oculography; altered blink reflexes; and a change in flicker fusion of visual images. At our hospitals, abnormal visual evoked responses have been found in 70 percent of patients with the clinical features of definite MS and 60 percent of patients with probable or possible MS. The corresponding figures for somatosensory evoked responses have been 69 percent and 51 percent, and for brainstem auditory evoked responses (usually prolonged interwave latency or decreased amplitude of wave 5), 47 percent and 20 percent, respectively according to our colleague K. Chiappa (see Chap. 2).

CT scanning may also demonstrate cerebral lesions, often unexpectedly. Doubling the dose of contrast material and delaying the scan for an hour postinfusion increases the yield of lesions during exacerbations of MS. Two points worth noting about the CT scan are that acute plaques can appear as contrast-enhanced ring lesions, simulating abscess or tumor, and that some contrast-enhanced periventricular lesions become radiologically ininvariant after steroid treatment, as occurs also with CNS lymphoma.

As mentioned earlier, the ancillary examinations in common use—MRI, evoked potentials, and oligoclonal bands in the CSF—have broadened the criteria for the diagnosis of MS. Often these procedures disclose the presence of multiple plaques when clinical examination has failed to do so. Stated differently, the time-honored rule that the diagnosis of MS requires evidence of “lesions
scattered in time and space” is still valid, but the evidence now includes certain laboratory findings as well as purely clinical ones. Finally, it should be noted that no single laboratory procedure—including MRI, altered blood-brain barrier, immunoglobulin synthesis, and MBP in CSF—when viewed alone or at a single time is a totally reliable marker for MS.

Clinical Course and Prognosis

The intermittency of the clinical manifestations—the disease advancing in a series of attacks, each permitting less and less remission—is perhaps the most important clinical attribute of MS. Some patients will have a complete clinical remission after the initial attack, or, there may be a series of exacerbations, each with complete remission; such exacerbations may rarely be severe enough to have caused quadriplegia and pseudobulbar palsy. The average relapse rate is 0.3 to 0.4 attacks per year according to the calculations of McAlpine and Compston, but the interval between the opening symptom and the first relapse is highly variable. It occurred within 1 year in 30 percent of McAlpine’s cases and within 2 years in another 20 percent. A further 20 percent relapsed in 5 to 9 years, and another 10 percent in 10 to 30 years. Not only the length of this latent interval is remarkable but also the fact that the basic pathologic process can remain potentially active for such a long time.

Weinshenker and colleagues, on the basis of observations in 1099 MS patients over a 12-year period, have identified a number of features of the early clinical course that are predictive, in a general way, of the outcome of the illness. Perhaps not surprisingly, they found that a high degree of disability, as measured by the Kurtzke Disability Status Scale, was reached earlier in patients with a higher number of attacks, a shorter first interattack interval, and a shorter time to reach a state of moderate disability. Kurtzke had earlier reported that the feature most predictive of long-term disability was the degree of disability at 5 years from the first symptom.

Whether the aforementioned tests for serum antibodies against oligodendrocytes and myelin have the predictive value indicated by Berger and colleagues remains to be seen, but their results are provocative. Only 23 percent of patients who lacked these antibodies had further attacks after their first one, despite the presence of oligoclonal bands, whereas 95 percent of those who had both antibodies suffered a relapse at an average time of 7 months.

After a number of years there is an increasing tendency for the patient to enter a phase of slow, steady, or fluctuating deterioration of neurologic function, attributable to the cumulative effect of increasing numbers of lesions. However, in about 10 percent of cases the clinical course is almost evenly progressive from the beginning (primary progressive MS; see Thompson et al). In these latter cases the disease usually takes the form of a chronic asymmetrical spastic paraparesis and probably represents the most frequent type of obscure myelopathy observed by the authors. In Thompson’s review of primary progressive MS, there was little change over time in the MRI findings, a negligible response to therapy, and a poor outcome. However, the validity of a fundamental distinction between relapsing and progressive MS is inevitably called into question since some lesions are silent and their accretion over time could be gradual. The frequency with which acute MS blends into the progressive variety has already been emphasized. (See earlier comments on page 772 regarding the pathologic distinctions between types of MS.)

Contrary to commonly held opinion, pregnancy does not have an adverse effect on MS. In fact, pregnancy is typically associated with clinical stability or even with improvement (as it is in a number of autoimmune diseases). The average relapse rate in established cases declines in each trimester, reaching a level less than one-third of the expected rate by the third trimester. However, there appears to be an increased risk of exacerbations, up to twofold, in the first few months postpartum (see Birk and Rudick). An extensive study of 269 pregnancies by Conflavreux and colleagues established a rate of relapse of 0.7 per woman per year before pregnancy and rates of 0.5 in the first, 0.6 in the second, and 0.2 in the third trimester, the rate then increasing substantially to 1.2 in the first 3 months postpartum.

The duration of the disease is exceedingly variable. A small number of patients die within several months or years of the onset, but the average duration is in excess of 30 years. A 60-year appraisal of the resident population of Rochester, Minnesota, disclosed that 74 percent of patients with MS survived 25 years, as compared with 86 percent of the general population. At the end of 25 years, one-third of the surviving patients were still working and two-thirds were still ambulatory (Percy et al). Other statistical analyses have given a less optimistic prognosis; these have been reviewed by Matthews. Patients with mild and quiescent forms of the disease are, of course, less likely to be included in such surveys. Although exceptional, one of our patients relapsed and developed massive brainstem demyelination and coma after 30 years (confirmed by postmortem examination), and cases of an aggressive myelopathy that appears after years quiescence are well known.

No environmental, dietary, or activity-related changes are known to alter the course of the illness.

Differential Diagnosis

In the usual forms of MS—that is, in those with a relapsing and remitting course and evidence of disseminated lesions in the CNS—the diagnosis is rarely in doubt. Meningovascular syphilis, certain rare forms of cerebral arteritis, vascular malformations such as cavernous angiomas of the brainstem or spinal cord with multiple episodes of bleeding, brain lymphoma, lupus erythematosus, the antiphospholipid antibody syndrome, and Behçet disease simulate relapsing MS, and each of these has its own characteristic and diagnostic features. The list can be expanded by the inclusion of corticosteroid-responsive cerebral lymphoma, intravascular lymphoma, and the numerous causes of multiple, well-demarcated white matter abnormalities on MRI, such as embolic infarcts, progressive multifocal leukoencephalopathy, Lyme disease, sarcoid, tumors, etc. Difficulties are most likely to arise when the standard clinical criteria for the diagnosis of MS are lacking, as occurs in the acute initial attack of the disease and in cases with an insidious onset and slow, steady progression. Other features that call for caution in diagnosis of MS are an absence of symptoms and signs of optic neuritis, the presence of widespread amyotrophy, entirely normal eye movements, a hemianopic field defect, pain as the predominant symptom, and a progressive nonremitting illness that begins in youth. Other points against MS are fever and nonneurologic features such as joint inflammation, skin rash, Sicca syndrome, or evidence of peripheral neuropathy.

As has been stated, the initial attack of MS may mimic acute labyrinthine vertigo or tic douloureux (trigeminal neuralgia). Careful neurologic examination of such patients usually discloses other signs of a brainstem lesion; the CSF examination may be particu-
larly helpful in these circumstances. Extensive brainstem demyelination of subacute evolution, involving tracts and cranial nerves sequentially, may be mistaken for a pontine glioma. With brainstem symptoms of acute onset, there may be difficulty in distinguishing an MS plaque from a small infarction due to a basilar branch occlusion. In several patients that we have observed, recurrent bleeding from cavernous vascular malformations and small brainstem arteriovenous malformations simulated MS. Only with MRI, visualization of blood products surrounding the small vascular lesions may the diagnosis be clarified (see Fig. 34-26). Sequential MRIs and the course of the illness settle the matter; symptoms of brainstem MS remit as a rule, and to a surprisingly complete degree in many cases.

Disseminated encephalomyelitis (see further on) is an acute illness with widely scattered small demyelinating lesions, but it is self-limited and monophasic; furthermore, fever, stupor, and coma, which are characteristic of severe cases, rarely occur in MS. The encephalomyelitis may, however, progress for several weeks, making the distinction from MS difficult.

In systemic lupus erythematosus and rarely in other autoimmune diseases (mixed connective tissue disease, Sjögren syndrome, scleroderma, primary biliary cirrhosis), there may be multiple lesions of the CNS white matter. These may parallel the activity of the underlying immune disease or the level of autoantibodies, particularly those against native DNA or phospholipids, but myelitis or lesions in the cerebral hemispheres are known to occur before other organ systems are affected. Conversely, between 5 and 10 percent of MS patients have antinuclear or anti-double stranded DNA antibodies without signs of lupus, but the significance of this finding is not at all clear. In addition, it has been pointed out that the relatives of patients with MS have a higher than expected incidence of autoantibodies of various types, suggesting an as yet unproved connection between autoimmune disease and MS. On MRI, the lesions of lupus and of antiphospholipid antibody syndrome appear similar to plaques, and both the optic nerve (rarely) and the spinal cord may be involved, even repeatedly, in a succession of attacks resembling MS. Nevertheless, in our pathologic material, the lesions represent small zones of infarct necrosis rather than demyelination and are traceable to small- vessel occlusion or cardiogenic embolism. In a few instances, inflammatory demyelination without vascular changes may be seen. It is best for the moment to consider these as special vascular manifestations of lupus or related diseases that mimic MS.

Periarteritis nodosa or vasculitis confined to the nervous system may produce multifocal lesions simulating MS. The distinction may be particularly difficult in rare instances of the vasculitic process in which the neurologic manifestations take the form of a relapsing or steroid-responsive myelitis. In these cases, the CSF may contain 100 or more white blood cells per cubic millimeter and there may be no evidence of disease elsewhere in the nervous system. Occasionally, a young individual with Lyme disease may have complaints of inordinate fatigue and vague neurologic symptoms coupled with bright lesions on the T2-weighted cranial MRI. Close attention to the characteristic history (rash, arthritis, etc.) and serologic findings should permit the distinction of the two diseases.

The distinguishing features of Behçet disease are recurrent iridocyclitis and meningitis, mucous membrane ulcers of mouth and genitalia, and symptoms of articular, renal, lung, and multifocal cerebral disease. The chronic forms of brucellosis in the Mediterranean regions and Lyme borreliosis throughout North America and Europe may cause myelopathy or encephalopathy with multiple white matter lesions on imaging studies, but in each case the history and other features of the disease help to identify the infectious illness (see Chap. 32).

The *purely spinal form of MS*, presenting as a progressive spastic paraparesis, hemiparesis, or—in several of our cases—spastic monoparesis of a leg with varying degrees of posterior column involvement, is a special source of diagnostic difficulty. A tendency to affect older women has already been mentioned. Such patients require careful evaluation for the presence of spinal cord compression due to neoplasm or cervical spondylosis. Dural arteriovenous fistula is also a consideration. Radicular pain at some point in the illness is a frequent manifestation of these disorders and is much less frequent in MS. Pain in the neck, restricted mobility of the cervical spine, and severe muscle wasting due to spinal root involvement, as is sometimes seen in spondylosis, are almost unknown in MS. Moderate atrophy of the first dorsal interosseus muscles has, however, been commented on as a common finding in MS. As a general rule, loss of abdominal reflexes, impotence in males, and disturbances of bladder function occur early in the course of demyelinating myelopathy but late or not at all in cervical spondylosis. The CSF protein in the latter condition is apt to be significantly elevated, but the other typical protein abnormalities of MS are absent. The definitive tests are MRI and CT myelography and perhaps electromyography (EMG), which is sensitive to the radicular features of spondylosis. Every patient with progressive spastic paraparesis in whom the neurologic signs are limited to the spinal cord should be investigated by these methods. In a patient with subacute, saltatory, and painful myelopathy restricted to one level (usually thoracic), a search for an arteriovenous malformation or fistula may be required. A special problem arises when imaging procedures reveal a regional swelling of the spinal cord suggestive of a tumor, which happens occasionally with an episode of myelitis. In several of our patients, this finding has led to fruitless laminectomy. Sarcoidosis affecting the cord presents similar problems; steroid-responsive granulomatous lesions of sarcoid that follow a venous pattern in the cerebrum may cause confusion with MS when viewed by MRI. The subpial pattern of enhancement with gadolinium is helpful in identifying sarcoid.

The problem of differentiating chronic spinal MS from tropical spastic paraparesis (human lymphotropic virus, myelitis of the HTLV-1 type) and progressive familial spastic paraplegia may also arise occasionally. Amyotrophic lateral sclerosis (ALS) and subacute combined degeneration (SCD) of the cord should not be confused with MS. ALS can be identified by the presence of muscle wasting, fasciculations, and the absence of sensory involvement, while SCD is characterized by symmetrical involvement of the posterior and then lateral columns of the spinal cord, low serum levels of vitamin B12, gastric achlorhydria, the presence of multilobed polymorphonuclear cells, megaloblastic marrow and macrocytic anemia in many cases, high serum concentrations of methylmalonic acid and homocysteine, and defective absorption of vitamin B12, as determined by the Schilling test (page 995). Reports that vitamin B12 levels are marginally low in a proportion of MS patients have been suggested as reflecting an underlying disturbance of homocysteine metabolism, but this has not been confirmed (Vrethem).

Platybasia and basilar impression of the skull should also be considered in the differential diagnosis, but patients with these conditions have a characteristic shortening of the neck; careful radiographs of the base of the skull will be diagnostic. Neurologic syndromes resulting from the Chiari malformation, syringomyelia, and tumors of the foramen magnum, cerebellopontine angle, clivus, and
other parts of the posterior fossa have been misdiagnosed as MS. In each of these instances, a solitary, strategically placed lesion may give rise to a variety of neurologic symptoms and signs referable to the lower brainstem and cranial nerves, cerebellum, and upper cervical cord, giving the impression of dissemination of lesions. It is an excellent clinical rule that a diagnosis of MS should be made with caution when all the patient’s symptoms and signs can be explained by a single lesion in one region of the neuraxis. Occasionally MS may be confused with the hereditary ataxias, particularly the spinocerebellar types. The latter are generally distinguished by their familial incidence and other associated genetic traits; by their insidious onset and slow, steady progression; and by their relative symmetry and stereotyped clinical pattern. Intactness of abdominal reflexes and sphincter function and the presence of pes cavus, kyphoscoliosis, and cardiac disease are other features that favor the diagnosis of a heredodegenerative disorder (see Chap. 39). Finally, as mentioned above, the periventricular lesions of cerebral lymphoma—an increasingly common tumor—and intravascular lymphoma (page 565) may closely resemble MS plaques on MRI and may also produce a multifocal, relapsing, steroid-responsive illness of the CNS. This last disease has been associated at times with oligoclonal bands in the spinal fluid.

With routine use of MRI and its central use for the diagnosis of MS, the issue of interpreting multiple white matter lesions arises frequently. As already discussed, numerous small, radically oriented and periventricular lesions are most suggestive of MS. Multifocal subcortical lesions, however, also arise in diverse processes, such as granulomatous angiitis of the nervous system, lymphoma, sarcoid, Lyme, antiphospholipid antibody syndrome, lupus, polyarteritis nodosa, and others. Notably, most of these processes cause small infarctions; others fluctuate in appearance with the use of steroids. The periventricular changes of chronic hypertension in the elderly are more confluent and diffuse than MS plaques, as discussed earlier, but when problems arise in differentiating the two, the patient’s age and the sparing of the corpus callosum and immediately adjacent white matter are hints to the vascular-glotic process. The difficulty of misinterpreting as a tumor a nodular enhancing mass of the acute MS lesion in the cerebrum has already been mentioned.

Careful clinical appraisal will usually lead to accurate diagnosis, but the label of MS should not be attached to a patient until the evidence is unequivocal. Once such a label is applied, it is difficult to discard, and since the diagnosis of MS will explain almost any subsequent neurologic event, attention may be directed away from consideration of another, perhaps more treatable disease.

**Treatment**

As one might expect, numerous forms of treatment have been proposed over the years, and many were thought to be successful, no doubt because of the remitting nature of the disease. To enumerate them all here would serve no useful purpose. The many therapeutic trials of recent years, utilizing mainly anti-inflammatory and immunosuppressive drugs, have been critically reviewed by Matthews and by Ebers and more recently by Rudick and colleagues. On the basis of controlled clinical trials, only adrenocorticotropic hormone (ACTH), methylprednisolone, prednisone, cyclophosphamide, copolymer, IFN-β, mitoxantrone and now, natalizumab have proved to have a beneficial effect on the disease and on MRI lesions each in specific circumstances.

Some current notions suggest that the definition of distinct clinical subsets of MS may be important in selecting therapy. Typical MS that is associated with episodic inflammation (relapsing-remitting) will probably be most responsive to immunomodulatory therapy. On the other hand, these measures may be less effective for chronic progressive subtypes. Indeed, while immunomodulatory therapies have shown at least short-term benefit in relapsing-remitting disease, none—with limited exceptions—has been clearly beneficial in chronic progressive MS. Therefore, as discussed earlier, therapy may be guided by the nature of the disease in each individual.

**Corticosteroids** Under the influence of corticosteroids, recovery from an acute attack, including an attack of optic neuritis, appears to be hastened. However, a substantial group of patients with acute exacerbations fail to respond; in others, benefit is not apparent for a month or longer after the course of treatment has been completed. There is limited evidence that steroids have a significant effect on the ultimate course of this disease or that they prevent recurrences. Accordingly, there is limited justification for steroid treatment over a period of many months or years except in those frequent cases where withdrawal of the medication consistently leads to relapse (alternative diagnoses should be considered in this event). It should be noted, however, that in a study of intravenous methylprednisolone administered at 1 g/day for 5 days per month over 5 years, there was a reduction in disability as well as in the degree of brain atrophy and total volume of hypodense lesions on T1-weighted MRI (Zivadinov).

As to the dosage of corticosteroids for an acute attack, it has seemed to us that initially a high dose is more effective, but this has been disputed by others, as noted below. The intravenous administration of massive doses of methylprednisolone (a bolus of 500 to 1000 mg daily for 3 to 5 days), followed by high oral doses of prednisone (beginning with 60 to 80 mg daily and tapering to a lower dosage over a 12- to 20-day period) is generally effective in aborting or shortening an acute or subacute exacerbation of MS or of optic neuritis. This plan is probably as effective as, and far less cumbersome than, the administration of ACTH, which was popular during the 1970s. When it is impractical to administer parenteral methylprednisolone, one may substitute oral methylprednisolone—48 mg in a single daily dose for 1 week, followed by 24 mg daily for 1 week, and finally 12 mg daily for 1 week—or the equivalent amount of prednisone (Barnes et al). This has the added advantage of avoiding hospitalization; however, we have the impression that severe attacks, especially of myelitis, respond more quickly to high-dose intravenous medication. It can be stated that a randomized trial comparing oral and intravenous methylprednisolone in acute relapses of MS has demonstrated no clear advantage of the intravenous regimen (Barnes et al).

We attempt to limit the period of corticosteroid administration to 2 to 3 weeks or less but prolong the period of tapering the drug if neurologic signs return. This brief period of corticosteroid administration generally produces few adverse effects, but some patients complain of insomnia and a few will develop depressive or manic symptoms. Patients who, because of clinical relapse on withdrawal of the medication, require treatment for more than several weeks are subject to the effects of hypercortisolism, including the facial and truncal cosmetic changes of Cushing syndrome, hypertension, hyperglycemia and erratic diabetic control, osteoporosis, aseptic necrosis of the acetabulum, and cataracts; less often, there may be gastrointestinal hemorrhage and activation of tuberculosis. Modest potassium replacement is advisable. Alternate-day steroid
treatment offers little benefit in our experience. However, pulses of high-dose intravenous steroids, as described above, administered once each month, seem to keep some patients from having relapses and are better tolerated than the continuous administration of oral medication. It must be acknowledged that the corticosteroid regimens and dosages in common use are derived from anecdotal experience (the Optic Neuritis Treatment Trial being an exception) and that certain patients appear, at least for a period of time, to respond better to one or another method of treatment.

**Treatment of Optic Neuritis**

The Optic Neuritis Treatment Trial, reported by Beck and colleagues, cautioned against the use of oral prednisone in the treatment of acute optic neuritis (see also Lessell). In this study it was found that the use of intravenous methylprednisolone followed by oral prednisone did indeed speed the recovery from visual loss, although at 6 months there was little difference between patients treated in this way and those treated with placebo. They reported that treatment with oral prednisone alone slightly increased the risk of new episodes of optic neuritis. In a subsequent randomized trial conducted by Sellebjerg and colleagues, it was found that methylprednisolone 500 mg orally for 5 days had a beneficial effect on visual function at 1 and 3 weeks. However, at 8 weeks, no effect could be shown (compared with the placebo-treated group), nor was there an effect on the subsequent relapse rate.

**Interferon Beta and Copolymer I**

These forms of treatment for patients with relapsing-remitting MS modestly alter the natural history of the disease. IFN-β–1b to patients with the secondarily progressive type of MS; progression of the disease was delayed for 9 to 12 months in a study period of 2 to 3 years.

The treatment of relapsing-remitting MS with IFN-β–1a (a glycosylated mammalian-cell product, Avonex) is equally effective and has the advantage that it may be taken once weekly as an intramuscular injection (PRISMS Study Group). The dose currently used is 30 mg, or 6.6 million units. Copolymer I (glatiramer acetate; Copaxone), which was synthesized to mimic the actions of myelin basic protein, is a putative autoantigen in MS, is given daily in subcutaneous doses of 20 mg. Glatiramer acetate may be particularly useful in patients who become resistant, i.e., develop antibodies to IFN-β (Rudick et al). The rate of such antibody emergence varies directly with the frequency of use of interferon: after a period of years, 30 percent of patients demonstrate antibodies with daily administration, 18 percent with alternate-day use, and less than 5 percent with weekly use. More recent changes in the preparation of interferon have led to reported rates of only 2 percent with antibodies after 1 year of use. There is some evidence that the presence of these antidrug antibodies diminishes the effectiveness of interferon. Antibodies do not develop to glatiramer acetate, and this has been emphasized as a relative advantage of the latter drug.

Overall, the side effects of these interferon agents are modest, consisting mainly of flu-like symptoms, sweating, and malaise beginning several hours after the injection and persisting for up to 14 h; they are reduced by nonsteroidal anti-inflammatory drugs and tend to abate with continued use of the agents. Nevertheless, some patients cannot tolerate them. A few migraineurs complain of exacerbation of their headaches. There may also be a tendency to depression in susceptible patients treated with interferon, and in our experience, this information, when openly discussed with the patient, has sometimes influenced the decision regarding choice of treatment. A rare but notable problem is the induction of a “systemic capillary leak syndrome” in patients with a monoclonal gammopathy who receive interferon. With more than weekly use, there may be an increase in liver function enzymes. Patients receiving glatiramer acetate should be warned of an infrequent complication consisting of flushing, chest tightness, dyspnea, palpitations, and severe anxiety. Injection site reactions occur with both classes of drugs but are rarely troublesome if the sites are rotated.

The salutary effects of treatment are definite though not overly impressive. These issues have been summarized by Hughes and Sharrack. Treatment is somewhat disruptive and quite expensive. Although most writers on the subject indicate that virtually all patients with proven MS should be treated soon after the diagnosis is established, the long-term effects on the illness still remain to be clarified. Nonetheless, the consistency with which various studies have demonstrated a reduction in relapses and in the accumulation of MRI lesions is notable. From these studies, the concept has emerged that subclinical lesions are of importance and that, over time, cognitive decline and neurologic deficits are more likely to occur if the rate of progression is not reduced by treatment. There are few circumstances where such treatment is mandated immediately and we allow enough time for the patient to consider the alternatives. The endless discussions about the superiority of weekly, every-other-day, or daily medications cannot be resolved except to say that more frequent administration is probably marginally better. In the case of interferon, however, it leads to a higher rate of antibody production over years. With all of these treatments it should be acknowledged that there is no certain correlation between the number of relapses and the ultimate disability despite authoritative statements to the contrary (see Confavreux et al, 2000).

The need to treat patients with optic neuritis alone with interferon has not been satisfactorily resolved. We have generally avoided this approach except in a few patients with repeated episodes involving both eyes at various times. Some guidance is given by the CHAMPS trial, which examined the effect of interferon (weekly) in patients with a first episode of optic neuritis and at least two lesions on MRI that were compatible with MS. Over 3 years, there was a modest reduction in clinical progression or relapse from 37 percent to 28 percent; if further MRI lesions were included, the difference from placebo treatment was even greater. If nothing else, this points to the value of a cerebral MRI in patients who have their first optic attack.

**Immunosuppressive Drugs**

A number of agents that modify immune reactivity have been tried, with limited success. Drugs such as azathioprine and cyclophosphamide, as well as total lymphoid irradiation, have been given to small groups of patients and seem to have improved the clinical course of some (Aimard et al, Hauser et al, Cook et al). However, the risks of prolonged use of immunosuppressive drugs, including a chance of neoplastic change, will probably preclude their widespread use. The careful study by the British and Dutch Multiple Sclerosis Azathioprine Trial Group attributed no significant advantage to treatment with this drug. For the chronic, progressive phase of the disease, an MS study group has reported a modest delay in the advance of the disease after a 2-year trial of prednisolone and cyclophosphamide. They caution,
however, that the “burdensome and potentially serious toxicity must temper consideration of its use in this disease.” At least one subsequent blinded, placebo-controlled study with cyclophosphamide has failed to show any benefit. In one trial involving patients with chronic progressive MS, weekly low-dose oral methotrexate has made a slight clinical difference and produced some reduction in the volume of cerebral lesions on the MRI compared with control cases (Goodkin et al). Because this regimen is well tolerated, it may still have some use in otherwise untreatable progressive cases.

Several new drugs have been introduced for the treatment of MS, but they have not been widely adopted and their role, while provocative, has not been clarified. Among these, mitoxantrone, a drug with broad immunosuppressant and cytotoxic activity used for various cancers, has attracted interest, because one study has shown a slight beneficial effect on the progressive form of the disease (Hartung et al). Some have disputed the interpretation of these results; additionally, there is little effect on the number of MRI lesions. Mitoxantrone is well tolerated and has the advantage of requiring administration one dose every 3 months (12 mg/m² intravenously); but it is known from experience with cancer treatment that the total dose is limited by several cardiotoxic effects, including congestive heart failure and arrhythmias. It is therefore given for only 2 years.

**Natalizumab** A novel approach to treatment is the use of natalizumab, an integrin antagonist used in rheumatoid arthritis, which blocks lymphocyte and monocyte adhesion to endothelial cells and their migration through the vessel wall. In a study that ran for 6 months, Miller and colleagues (2003) were able to demonstrate a slight reduction in the number of relapses and a marked effect on MRI lesions.

A recent double-blind, placebo-controlled study of 942 patients with relapsing-remitting MS (the AFFIRM study) showed a 68 percent reduction in relapses, an 80 percent reduction in new or enlarging T2 cerebral lesions and a 96 percent reduction in gadolinium-enhancing lesions on MRI after a year. Although this data is preliminary, it represents a twofold improvement in efficacy compared to what has been reported with interferon and glatiramer acetate. There was a 2 percent rate of anaphylactic reactions. Moreover, another preliminary study suggests that the use of interferon and natalizumab may give even better results (the SENTINEL study).

The advantages are once monthly intravenous treatments and a virtual lack of side effects (undoubtedly some will emerge as more experience is gained). We do not anticipate encouraging patients who are doing well on interferon or glatiramer to switch to natalizumab, but it seems reasonable to use the drug for newly diagnosed cases of relapsing-remitting disease. At this time, although this drug is overtaking other treatments, indications for its use are still being evaluated because of rare cases of PML in patients taking interferon and natalizumab for long periods.

**Other Therapies** There are no valid studies to substantiate claims that have been made for the value of synthetic polypeptides other than copolymer, for hyperbaric oxygen, low-fat and gluten-free diets, or linoleate supplementation of the diet. As mentioned under “Acute Multiple Sclerosis,” there may be a role for plasma exchange (Rodriguez et al) and perhaps immunoglobulin in fulminant cases, but these have not been tested rigorously. One limited trial has shown some benefit, in patients with relapsing-remitting disease, of monthly infusions of intravenous immunoglobulin (0.2 g/kg) for 2 years (Fazekas et al).

**General Measures** These include the provision of an adequate period of bed rest and convalescence to ensure maximum recovery from the initial attack or exacerbation, prevention of excessive fatigue and infection, the use of all possible rehabilitative measures to postpone the bedridden stage of the disease (braces, chairs, ramps, lifts, cars with manual controls, etc.), and meticulous attention to the prevention of bedsores in the bedridden patient by the use of alternating-pressure mattresses, silicone gel pads, and other special devices.

Fatigue, a common complaint of MS patients, particularly in relation to acute attacks, responds to some extent to amantadine (100 mg morning and noon), modafinil (200 to 400 mg/day), or pemoline (20 to 75 mg each morning). Fatigue and weakness are both reportedly ameliorated with potassium channel blockers (3, 4-diaminopyridine), although access to these non-FDA-approved compounds is difficult and they are epileptogenic at high doses. Confirmation of their benefit will be required before they come into general use.

Disorders of bladder function may raise serious problems in management. Where the major disorder is one of urinary retention, bethanechol chloride is helpful. In this situation, monitoring and reducing the residual urinary volume is an important means of preventing infection; volumes up to 100 mL are generally well tolerated. Some patients with severe bladder dysfunction, particularly those with urinary retention, benefit from intermittent catheterization, which they can learn to do themselves and which lessens the constant risk of infection from an indwelling catheter. More often the problem is one of urinary urgency and frequency (spastic bladder), in which case the use of propantheline (Pro-Banthine) or oxybutynin ( Ditropan) may serve to relax the detrusor muscle (Chap. 26). These drugs are best used intermittently. Severe constipation is best managed with properly spaced enemas. Often a program of bowel training can be successfully undertaken. Sexual dysfunction, a very common problem in men with MS, has been successfully treated with sildenafil and similar drugs. When pain is a prominent symptom, its management follows the general principles of pain management outlined in Chap. 8. Carbamazepine or gabapentin are often helpful and these agents also reduce paroxysmal symptoms in MS.

In patients with severe spastic paralysis and painful flexor spasms of the legs, oral and then intrathecal infusion of baclofen through an indwelling catheter and implanted pump, as in other spastic states, is sometimes of value. The selective injection of botulinum toxin into the most hypertonic muscles may help some patients. Patients with lesser degrees of spasticity have benefited from the oral administration of baclofen. Failing this measure, one of several surgical procedures—dorsal rhizotomy, myelotomy, crushing of the obturator nerves, and, most useful of all in severe cases, intrathecal baclofen infusion by pump—may give relief for a prolonged period.

The severe and disabling tremor that is brought out by the slightest movement of the limbs, if unilateral, can be managed surgically by ventrolateral thalamotomy or implanted stimulator of the type used for the treatment of Parkinson disease. Most surgical series report that about two-thirds of patients achieve a satisfactory reduction in their intention tremor (Crichtley and Richardson; Geny et al). In the experience of others, the results have not been quite as reliable as this. The series of Hooper and Whittle, only 3 of 10 MS patients who underwent thalamotomy for a severe tremor had sustained improvement. Hallett and colleagues have reported that severe postural tremor of this type can be improved by the ad-
ministration of isoniazid (300 mg daily, increased by weekly increments of 300 mg to a dose of 1200 mg daily) in combination with 100 mg of pyridoxine daily. How isoniazid produces its beneficial effects is not known, and careful monitoring of liver tests is required. Variable success may also be achieved with carbamazepine or clonazepam. Necessary vaccinations are not interdicted in patients with MS.

The importance of an understanding and sympathetic physician in the care of patients with a chronic incapacitating neurologic disease of this kind cannot be overemphasized. Enlisting the support of physical and occupational therapists, visiting nurses, and social workers can be equally important. From the beginning, when patients first inquire about the nature of their illness, they require advice about their daily routine, marriage, pregnancy, the use of drugs, inoculations, and so on. As indicated earlier, the term MS should not be introduced until the diagnosis is certain, and then it should be qualified by a balanced explanation of the symptoms, stressing always the optimistic aspects of the disease. Most patients desire an honest appraisal of their condition and prognosis; some consider the uncertainty of their prognosis worse than their actual disability.

**ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)**

**Postinfectious, Postexanthem, Postvaccinal Encephalomyelitis**

Some of these terms, used originally to refer to the neurologic sequelae of infectious fevers, were introduced into medicine in the late nineteenth century, but it was not until the late 1920s that Perdrau, Pette, Greenfield, and others identified a type of pathologic reaction common to a number of exanthems and vaccines. The current view of this entity is that it represents an acute inflammatory and demyelinating disease, distinguished pathologically by numerous foci of demyelination scattered throughout the brain and spinal cord and some restricted to the cerebellum or spinal cord. These lesions vary from 0.1 to several millimeters (when confluent) in diameter and invariably surround small and medium-sized veins. The axons and nerve cells are more or less intact. Equally distinctive is the perivenular inflammatory reaction of lymphocytes and mononuclear cells. The adjacent regions of white matter are invaded by monocytes and microglia corresponding to the zones of demyelination. Multifocal meningeal infiltration is another invariable feature but is rarely severe in degree. With the exception of this last feature, ADEM is indistinguishable on histopathologic grounds from acute MS. It is the setting, further course, and then certain special features of each that set them apart. Indeed, even the monophasic nature of ADEM and its clear separation from MS on clinical grounds has been questioned by Schwarz and colleagues, who found that 14 of 40 adults later developed clear signs of MS, usually within a year.

An acute encephalitic, myelitic, or encephalomyelitic process of this type is observed in a number of clinical settings and is more common in children. In our own experience we have found that most often in children the disease follows a febrile illness by days or weeks; this is less often the case in adults. In the originally described form, it occurred within a few days of onset of the exanthem of measles, rubella, smallpox, or chickenpox. Prior to widespread immunization against measles, an epidemic in a large city might have resulted in 100,000 cases of measles and clinically evident neurologic complications in 1 in 800 to 1 in 2000 cases. The mortality among patients with such complications ranged from 10 to 20 percent; about an equal number were left with persistent neurologic damage. The neurologic complications of measles alone provide sufficient justification for immunization against the disease. The incidence of encephalomyelitis was less following chickenpox and rubella and much less following mumps (the latter never seen in our pathologic material). In the past, a similar illness was observed to follow vaccination against rabies and smallpox and, reportedly, after administration of tetanus antitoxin (rare), as discussed further on. Now, however, most cases, clinically and pathologically indistinguishable from these two categories of ADEM, appear to develop after seemingly banal respiratory infections and after documented infections with Epstein-Barr, cytomegalovirus, and *Mycoplasma pneumoniae* and even HIV (Narisco et al); occasionally there is no clearly defined preceding illness or inoculation. Many if not most instances of acute transverse myelitis may represent the same postinfectious process. The neurologic illness may coincide with the later stages of the manifestations of the infection, in which case the term *parainfectious* may be appropriate.

Irrespective of the clinical setting in which it occurs, disseminated encephalomyelitis in its severe form is of grave import because of the significant rate of neurologic defects in patients who survive. In children, recovery from the acute stage is sometimes followed by a permanent disorder of behavior, mental retardation, or epilepsy; paradoxically, most adults make good recoveries. The cerebellitis and acute ataxia that follow chickenpox and other infections are more benign, normally clearing over several months, and may represent a different process, as discussed further on.

**Pathogenesis** The pathogenesis of disseminated encephalomyelitis is still unclear despite its obvious association with viral infections. In the exanthem cases, a definite interval usually separates the onset of disseminated encephalomyelitis from the onset of the rash; also, the pathologic changes are quite different from those of viral infections and virus is rarely if ever recovered from the CSF or brains of patients with disseminated encephalomyelitis. For these reasons it is believed that the disorder represents an immune-mediated complication of infection rather than a direct infection of the CNS, a process comparable to the Guillain-Barré syndrome. However, as discussed in Chap. 33, new molecular techniques have been able to detect fragments of DNA from varicella zoster virus, *Mycoplasma*, and other organisms, so that the question of pathogenesis cannot be answered with finality. Nevertheless, Waksman and Adams found the pathologic changes in these two circumstances—postinfectious demyelination and direct viral infection of the CNS—to be quite different.

A laboratory model of the disease, experimental allergic encephalomyelitis (EAE), has been produced by inoculating animals with a combination of sterile brain tissue and adjuvants. The experimental disease appears most commonly between the eighth and fifteenth days after sensitization (see below) and is characterized by the same perivenular demyelinating and inflammatory lesions that one observes in the human disease. Presumably the lesions are the result of a T-cell–mediated immune reaction to components of myelin or oligodendrocytes. Recently, evidence of antibody binding, complement activation, and eosinophilic infiltration has led to the notion that ADEM is a humoral disease, in contrast to the cellular mechanism that has been proposed for MS but further confirmation of this notion is required (see Luchinetti et al).

The notion that EAE and disseminated encephalomyelitis have a similar pathogenesis has received support from the observations of R. T. Johnson and colleagues. They studied 19 patients...
with postinfectious encephalomyelitis complicating natural measles virus infections. Early myelin destruction was demonstrated by the presence of MBP in the CSF, and lymphocyte proliferative responses to MBP were found in 8 of 17 patients tested. Similar responses were observed in patients with encephalomyelitis after rabies vaccine and after varicella and rubella virus infections, suggesting a common immune-mediated pathogenesis. Moreover, the patients with postmeasles encephalomyelitis showed a lack of intrathecal synthesis of antibody against measles virus, indicating that the neurologic disease was not dependent on viral replication within the CNS.

Clinical Features  The encephalitic form is expressed more fully in children than in adults. As an acute infectious illness is resolving or after a latency of several days or longer, there is the abrupt onset, over hours or a day or two, of confusion, somnolence, and sometimes convulsions with headache, fever, and varying degrees of neck stiffness. Ataxia is common but myoclonic movements and choreoathetosis are observed less frequently. In more severe cases, stupor, coma, and at times decerebrate rigidity may occur in rapid succession. In many cases the disease is less severe and the patient suffers a transient encephalitic illness with headaches, confusion, and slight signs of meningeal irritation.

The latency between infection and the first neurologic symptoms that it is acceptable to impute to this diagnosis is a matter of debate, but there are convincing cases (postexanthematous) in which the two phases of illness are separated by 3 or 4 weeks; several days is more typical, as noted below. Curiously, in the encephalitic form, new signs may continue to appear for up to 2 or 3 weeks from the onset. This is emphasized in the series of affected children collected by Hynson and colleagues. The imaging changes may also display delayed or continued evolution, as noted below. These authors note that ataxia was the most common initial feature in their cases, which is not entirely in accordance with our experience (see below).

In the myelitic form (postinfectious myelitis, acute transverse myelitis), there is partial or complete paraplegia or quadriplegia, diminution or loss of tendon reflexes, sensory impairment, and varying degrees of paralysis of bladder and bowel. A syndrome that simulates anterior spinal artery occlusion (spastic paraplegia and loss of pain sensation below a level on the trunk but tending to spare large-fiber sensibility) is not uncommon in our experience. Also, we have cared for a few patients with a limited sacral form of postinfectious myelitis. Midline back pain may be a prominent symptom at the onset.

In both the encephalitic and myelitic types, there may be slight fever, particularly in the more aggressive cases and in younger individuals, where we have seen temperatures reaching 39.4°C (103°F), but the peripheral white blood cell count is normal if the initiating infection has resolved. A few of our cases have had elevated sedimentation rates, but it is not possible to know whether this reflects the precipitating infection. Separating these two entities may nonetheless be difficult, especially in children who have more of a tendency to develop fever and convulsions with ADEM. Either process may be associated with an aseptic meningitis.

The CSF shows a slight increase in lymphocytes and protein content, but these are highly variable, with a few of our cases having only an increase in protein and no cells and others having up to several hundred cells. The MRI shows several bilateral confluent white matter lesions in both cerebral hemispheres early in the course of ADEM (Fig. 36-3); when these are large and numerous, the diagnosis is more certain. The lesions all appear to be of similar age, but we cannot account for several cases we have seen in which serial MRIs show new lesions accumulating over 2 or 3 weeks, as already noted. Moreover, as pointed out by Honkanemi and colleagues, there may be a delay of several days between the clinical manifestations and the first appearance of changes in the MRI, a situation to which we can attest. Whether a single lesion on MRI can be considered compatible with ADEM is unclear.

In the case of postexanthemencephalomyelitis, the syndrome generally begins 2 to 4 days after the appearance of the rash. Usually the rash is fading and other symptoms are improving when the patient, usually a child, suddenly develops a recrudescence of fever, convulsions, stupor, and sometimes coma. Less commonly, the pa-
tient may develop hemiplegia or a virtually pure cerebellar syndrome, as noted below (particularly after chickenpox), and occasionally a transverse myelitis, sphincteric disturbance, or other signs of spinal cord involvement. Choreaathetotic movements are seen infrequently. Likewise, optic neuritis is uncommon, but it does occur.

A variant of postinfectious encephalomyelitis that involves solely or predominantly the cerebellum deserves special comment. Typically, a mild ataxia with variable corticospinal or other signs appears within days of one of the childhood exanthems as well as after Epstein-Barr virus, *Mycoplasma, Legionella*, and cytomegalovirus infections and after a number of vaccinations and nondescript respiratory infections. It is described in detail on page 641 because it has a close relationship to certain viruses, particularly varicella, suggesting that some if not most cases are due to an infectious meningoencephalitis. Others—for example, following mycoplasmal infection—occur after a long latency and show pathologic changes that are consistent with a postinfectious demyelination. Thus it is possible that there may be two types of acute cerebellitis, one para- or postinfectious and the other due to a direct infection of the brain and meninges. The benign nature of the illness has precluded adequate pathologic examination, hence some of these statements are speculative.

**Differential Diagnosis** It must be re-emphasized that not all the neurologic complications of measles and other exanthems and acute viral infections are examples of postinfectious encephalomyelitis. As already noted, the illness is at times difficult to distinguish from viral meningoencephalitis. Infectious mononucleosis, herpes simplex, mycoplasmal infection, and other forms of encephalitis may all mimic the postinfectious variety. In some cases cerebrovascular disease (particularly cortical vein or dural sinus thrombosis), hypoxic encephalopathy, or acute toxic hepatoencephalopathy (Reye syndrome) is responsible for these complications. The Reye syndrome is usually not difficult to separate from postinfectious encephalomyelitis, even when it follows chickenpox or viral influenza, because of the normal CSF and high serum concentrations of liver enzymes and ammonia (see page 969). In a child, the first attack of febrile seizures in the course of an exanthematous illness may raise the suspicion of encephalitis or postinfectious encephalomyelitis.

**Postvaccinal Encephalomyelitis** Since late in the nineteenth century, it has been known that a severe form of encephalomyelitis may complicate the injection of rabies vaccine (“neuroparalytic accident”). Until quite recently, the vaccine in common use consisted of killed virus that had been grown in rabbit brain tissue. Encephalomyelitis occurred in about 1 in 750 patients inoculated with this vaccine, and about 25 percent of cases with this complication proved fatal. Alternative vaccines, made from embryonated duck eggs (and later from human diploid cells) infected with fixed viruses, contain very little or no nerve tissue and are almost free of neurologic complications. In developing countries, where less expensive brain-based vaccines are still in use, neuroparalytic accidents continue to occur. The observations of Hemachudha and colleagues indicate that the altered immune mechanism that is operative in the neuroparalytic accident is the same as that in postmeasles encephalomyelitis and experimental allergic encephalomyelitis.

There are numerous recorded instances in which the old rabies vaccine (with neural tissue) induced an attack of what subsequently appeared to be MS. Shiraki and Otani reported such examples from Japan. The evolution of symptoms was subacute, over a period of 2 to 4 weeks, and the demyelinative lesions were macroscopic—up to 1 to 2.0 cm in diameter—but composed of confluent perivenous lesions. The disease could be reproduced in dogs—persuasive evidence that one form of acute MS is a variant of ADEM.

Encephalomyelitis following vaccination against smallpox has been known since 1860, having occurred about once in 4000 vaccinations. This disease is now of historical interest only, insofar as smallpox has disappeared as a human illness worldwide. In the United States, there have been no new cases for years, and smallpox vaccination is no longer included as part of immunization schedules. Recent political events, which have resurrected a national program of vaccination, perhaps may cause the problem to recur if widespread immunizations are undertaken.

The association of the neurologic disorder with vaccination usually leaves the diagnosis in little doubt, and the characteristic combination of encephalitic and myelitic features will help to distinguish the condition from meningitis, viral encephalitis, and poliomyelitis. Rarely, an atypical case may mimic any one of these disorders. On occasion, the disease may suggest involvement of nerve roots and peripheral nerves and resemble acute inflammatory polyneuritis (Guillain-Barré syndrome). In fact, the rabies vaccine produced in South America from suckling mouse brain causes this type of peripheral nerve disease more often than encephalomyelitis.

Mundane inoculations such as those for influenza or hepatitis must have a very small rate of ADEM, judging from surveillance studies; Ascherio and colleagues were unable to find any increase in cases among two large studies of nurses who received hepatitis B vaccine. The absence of a clear connection of MS to vaccination has already been mentioned.

The mortality rate of postvaccinal encephalomyelitis is high, between 30 and 50 percent. If recovery occurs, it may be surprisingly complete. However, a significant proportion of patients show residual neurologic signs, mainly in the form of seizures, intellectual impairment, or behavioral abnormalities.

**Treatment** With regard to treatment of ADEM, the use of high-potency steroids appears to be the best choice, although controlled trials of this have not been carried out. Steroids, given before or immediately upon the appearance of neurologic signs, may modify the severity of experimental allergic encephalomyelitis; this provides the logic for their use in the human counterpart of this disease. However, the pathologic process cannot be altered once the first signs appear. Plasma exchange and intravenous immune globulin have also been successful in some fulminant cases (Kanter et al; Stricker et al) but only in a few we have observed.

**Acute Necrotizing Hemorrhagic Encephalomyelitis (Acute Hemorrhagic Leukoencephalitis of Weston Hurst)**

This, the most fulminant form of demyelinating disease, affects mainly young adults but also children. It is almost invariably preceded by a respiratory infection of variable duration (1 to 14 days), sometimes due to *M. pneumoniae* but more often following a mumps infection or of indeterminate cause. The neurologic symptoms appear abruptly, beginning with headache, fever, stiff neck, and confusion. These are followed in short order by signs of disease of one or both cerebral hemispheres and brainstem—focal seizures, hemiplegia or quadriplegia, pseudobulbar paralysis, and progressively deepening coma. Leukocytosis is usually present, sometimes reaching 30,000 cells per cubic millimeter, and the sedimentation rate is elevated. The CSF is often under increased pressure; cells vary in number from a few lymphocytes to a polymorphonuclear...
pleocytosis of up to 3000 cells per cubic millimeter; red cells may be present in variable numbers; protein content is increased, but glucose values are normal. Diagnosis is greatly facilitated by CT scanning and MRI, which reveal bilateral but asymmetrical large, confluent, edematous lesions in the cerebral white matter with a myriad of punctate hemorrhages in gray and white matter (Fig. 36-4). The size of the lesions, their hemorrhagic character, and the extent of the surrounding edema distinguish them from the typical postinfectious ADEM. In many other ways they are similar except for their severity. Many cases terminate fatally in 2 to 4 days, but in others survival is longer. Patients with a similar clinical picture who are thought to have the same disease on the basis of brain biopsy examinations have recovered with almost no residual symptoms. In one of the fatal cases reported by Adams et al, the illness evolved more slowly—over a period of 2 to 3 weeks—while another patient died with temporal lobe herniation within 12 h. A single recurrence of the disease after an interval of 2 years was observed in one of our cases.

Brain abscess, subdural empyema, focal embolic encephalomalacia, and acute encephalitis due especially to type 1 herpes simplex virus are the important considerations in the differential diagnosis.

Figure 36-4. Acute necrotizing hemorrhagic leukoencephalitis, mainly bilateral showing the large confluent hemorrhagic areas.

The pathologic findings are distinctive. On sectioning of the brain, the white matter of one or both hemispheres is seen to be destroyed almost to the point of liquefaction. The involved tissue is pink or yellow-gray and flecked with multiple petichial hemorrhages. Similar changes are often found in the brainstem and cerebellar peduncles and probably in the spinal cord (one form of acute necrotizing myelitis and Devic disease). On histologic examination, one finds widespread necrosis of small blood vessels and brain tissue around the vessels, with intense cellular infiltration, multiple small hemorrhages, and an inflammatory reaction in the meninges of variable intensity. The pathologic picture resembles that of disseminated encephalomyelitis in its perivascular distribution, with the added features of a more widespread necrosis and a tendency of lesions to form large foci in the cerebral hemispheres. The vascular lesions result in a characteristic exudation of fibrin into the vessel wall and surrounding tissue. It is possible that certain patients showing an explosive myelitic illness are suffering from a necrotizing lesion of similar type, but pathologic evidence in support of this view has been difficult to obtain. Fibrin exudation in an acute fatal hemorrhagic myelitis was present in a case examined by Adams and colleagues. We also have experience with a case of this nature that evolved in steps over several months, resulting in death, with a cellular reaction in the spinal fluid on each of several lumbar punctures. There was partial steroid responsiveness.

The etiology of this condition remains obscure, but its resemblance to other demyelinating diseases should be emphasized. The similarities of the histologic changes to those of disseminated encephalomyelitis, noted above, suggest that the two diseases are related forms of the same fundamental process. In fact, cases combining both types of pathologic change have been described (Fisher et al). The observations of Behan and colleagues—that the lymphocytes of a patient with postinfectious encephalomyelitis and of another patient with acute necrotizing hemorrhagic encephalitis underwent transformation to lymphoblasts in response to a pure encephalitogenic MBP—support the view that delayed hypersensitivity mechanisms are operative in both diseases. Earlier, Wakeman and Adams had demonstrated that the vascular lesions of experimental allergic encephalomyelitis could be converted to those of necrotizing encephalomyelitis by inducing a Schwartzman reaction (by intravenous injection of meningococcal toxin). It is also noteworthy that, among the small number of patients who have recovered from what appeared to be a typical necrotizing hemorrhagic encephalitis, a few have gone on to develop typical MS.

Treatment These points of similarity are sufficient to suggest that corticosteroids should be used in the treatment of acute necrotizing hemorrhagic encephalopathy; in several personally observed patients, we had the impression that they produced a favorable result. The use of plasma exchange and intravenous immunoglobulin, as for acute disseminated encephalomyelitis, is being explored and has had success in single reported cases when instituted early.

CHAPTER 37

THE INHERITED METABOLIC DISEASES OF THE NERVOUS SYSTEM

Advances in biochemistry and molecular genetics have led to the discovery of such a large number of metabolic diseases of the nervous system that it taxes the mind just to remember their names. Since the causes and mechanisms of the diseases included in this chapter (and in several that follow) are increasingly being expressed in terms of molecular genetics, it seems appropriate, by way of introduction, to consider briefly some basic facts pertaining to the genetics of neurologic disease. A complete account of this subject may be found in the four-volume text edited by Scriver and colleagues.

One must be reminded that the biochemistry of every human organism is unique (i.e., never duplicated) and that every person, in some particular way, has an inborn tendency to develop certain diseases. This constitutional predisposition, or diathesis, lies in the variations of DNA of the chromosomes of each cell. Knowledge of the molecular basis of this constitutional predisposition may ultimately provide the means of diagnosis, prevention, and perhaps treatment of many human diseases.

The diseases grouped in this chapter and the next represent four particular categories of genetic abnormality: (1) monogenic disorders determined by a single mutant gene that follow a mendelian pattern of inheritance; (2) multifactorial disorders, again following a mendelian pattern of inheritance but in which intrinsic (i.e., genetic) factors interact with exogenous environmental ones; (3) nonmendelian chromosomal aberrations, characterized by an excess, a lack, or a structural alteration of one or more of the 23 pairs of chromosomes (these are considered in the next chapter, with the developmental disorders); and (4) mitochondrial transmission of disease in a nonmendelian, mainly maternal pattern.

As stated in the monograph of Scriver et al., 6 to 8 percent of diseases in hospitalized children are attributable to single gene defects and 0.4 to 2.5 percent to a chromosomal abnormality. Another 22 to 31 percent have a disease thought to be gene-influenced. In the general population, when multifactorial inheritance of late-onset diseases is included, the latter figure rises to about 60 percent. Mitochondrial inheritance of mutations is much less frequent and has unusual patterns of transmission, mostly through maternal lines.

The nervous system is more frequently affected by a genetic abnormality than any other organ system, probably because of the large number of genes implicated in its development (an estimated one-third of all the genes in the human genome). Approximately one-third of all inherited diseases are neurologic to some extent; if one adds the inherited diseases affecting the musculature, skeleton, eye, and ear, the number rises to 80 to 90 percent.

Of the almost 6000 entities itemized in the 1998 edition of McKusick’s catalogue of inherited diseases, about 500 are identified as enzymopathies—i.e., mendelian disorders with a demonstrated primary enzyme defect. The latter constitute only one-third of the known recessive (autosomal and X-linked) disorders. Most of the enzymopathies become manifest in infancy and childhood; only a few appear as late as adolescence or adult life. Many damage the nervous system so severely that survival to adult years and reproduction are impossible, and some cause death in utero. As a group, these diseases—along with congenital anomalies (Chap. 38), birth injuries, epilepsy, disharmonies of development, and learning disabilities (Chap. 28)—make up the bulk of the clinical problems with which the pediatric neurologist must contend.

Autosomal and Sex-Linked Patterns of Inheritance

Traditionally, the recognition of these broad categories of genetically determined diseases has rested on their pattern of occurrence in families, segregated according to mendelian inheritance into autosomal dominant, autosomal recessive, and sex-linked types. Mutations of nuclear DNA account for the majority of heritable autosomal and sex-linked diseases described in this chapter, and they are remarkably diverse in nature. Some are lethal and, as mentioned, are therefore not transmitted to successive generations; others are less harmful and may conform to one of the classic mendelian patterns. The mutation may be large and result in duplication (or deletion) of a major part of a chromosome or even of the entire genome (diploidy), or it may create a third copy of the entire complement of genes (triploidy). Other mutations are very small, involving only a single base pair (“point mutation”). Between these two extremes are deletions or duplications that include a portion of a gene, an entire gene, or contiguous genes.

The factors conducive to mutations are poorly understood. An increasing age of the parent is important in relation to some mutations; the size, structure, and placement of the gene on the chromosome are important in others. A mutation of the DNA of a germ cell leaves unchanged the somatic phenotype of the individual in whom it occurs, but it may have a devastating effect on the descendents. Conversely, a DNA mutation of a somatic cell affecting only part of the cell population may change the individual harboring it but is not passed on to the descendents. Such an individual, with both normal cells and cells containing the mutant gene, is referred to as a mosaic. Mutations of somatic cells appear to be most pertinent to cancer and aging.

In the monogenic inheritance of all three mendelian patterns, the mutation usually causes an abnormality of a single protein. It may involve an enzyme, peptide hormone, immunoglobulin, collagen, or coagulation factor. Such abnormalities of single genes have been isolated in several hundred diseases, but little is known of their protein products. About one-quarter of these diseases are apparent soon after birth and more than 90 percent by puberty. More than half of them affect more than one organ. Of the 10 in every 1000 live births with genetic diseases, 7 are dominant, 2.5 are recessive, and the remainder are sex-linked.

Autosomal dominant mutations usually cause manifest disease in heterozygotes, but variations in the size of the gene abnor-
mality can produce any one of several phenotypes. This poses a challenge to the current clinical and pathologic classifications of disease. Moreover, an identical clinical syndrome may be traced to a gene on two different chromosomes. Even more surprising, an estimated 28 percent of all gene loci have polymorphic rather than monomorphic effects—that is, the same mutation has several different phenotypic expressions. Another problem is that of differentiating dominant from recessive inheritance. In small families, in which only one descendant is afflicted and the parent is seemingly normal, one may mistakenly conclude that the inheritance is recessive. Variable degrees of penetrance and expressivity are characteristic features of dominant patterns of inheritance but not of recessive ones. There is also a general tendency for dominantly inherited disease to first appear long after birth.

Autosomal recessive forms of inherited metabolic diseases, in contrast to dominant ones, occur only in the homozygous state (both alleles abnormal). They are usually characterized by an onset soon after birth. The basic abnormality in the recessively inherited diseases discussed in this chapter is more often an enzyme deficiency than an abnormality of some other protein.

In disorders of X-linked genes, in which the mutant gene affects mainly one sex, the female will suffer the same fate as the male if one X chromosome has been inactivated, as happens in most cells during embryonic development (the Lyon phenomenon). However, even if the abnormal X chromosome is not widely expressed, the female carrier may still exhibit minor abnormalities. In the latter case, sex-linked inheritance becomes difficult to distinguish from dominant inheritance. Also, sex linkage is deceptive when a disease is lethal to one sex. In contrast to autosomal recessive mutations, the biochemical abnormality has more often been one of a basic protein rather than an enzyme deficiency.

Multifactorial genetic diseases are also by nature familial. They may present as constitutional disorders with gene abnormalities located on several chromosomes (polygenic, or “complex genetics”). The precise number of such genes required to produce a given abnormality is not known, making the risk of inheritance difficult to calculate. Here also the relative contributions of genetic and environmental influences are highly variable. The methodology for identifying this category of genetic disease has usually required the comparison of large numbers of affected patients and controls or of progeny living with their biologic parents and those adopted by normal families at an early age. Monozygotic and dizygotic twin comparisons provide essential information about “risk genes.” The occurrence of many disorders that display high degrees of familial incidence, such as schizophrenia and Tourette syndrome, but do not strictly conform to classic genetic principles has been attributed to this type of complex genetics.

The Genetics of Mitochondrial Disease

In the past few decades, an entirely new type of genetic transmission relating to the DNA that lies in the mitochondria has been elucidated. Mitochondria contain their own extrachromosomal DNA, distinct from nuclear DNA. Mitochondrial DNA (“the other human genome”) is a double-stranded, circular molecule that encodes the protein subunits required mainly for translation of the proteins located on the mitochondrial inner membrane. Of the 37 mitochondrial genes, small in number by comparison with nuclear DNA, 13 partake in the cellular processes of oxidative phosphorylation and the production of adenosine triphosphate (ATP). A small number of genes in the cell’s nucleus also code for a considerable number of oxidative enzymes of the mitochondria, but their inheritance follows a mendelian pattern.

Each mitochondrion contains up to 10 ringed DNA molecules, and each cell, of course, contains numerous mitochondria. In the cell, mitochondria with mutant genes may exist next to normal mitochondria (heteroplasmy), a state that permits an otherwise lethal mutation to persist (Johns). The presence of either completely normal or completely mutant mitochondrial DNA is termed homoplasmy. The essential feature of mitochondrial genes and the mutations to which they are subject is that they are inherited almost exclusively through maternal lineage. This is explained by the transmission of virtually all mitochondria from the ovum at the time of conception. Moreover, mitochondrial DNA does not recombine, thus permitting the accumulation of mutations through maternal lines. Also, the replication and distribution of mitochondrial DNA during cell division does not follow the nuclear mitotic cycle. Instead, there are contributions during cell division from the genes of various mitochondria to the progeny of dividing cells. The combination of a heteroplasmic state and the capricious dispersion of mitochondria to daughter cells (replicative segregation) explains the variable expression of mitochondrial mutations in different tissues and in different regions of the nervous system as well as variations in the age of onset of the mitochondrial diseases.

The genetic error in each of the mitochondrial diseases is most often a single point mutation that leads to the alteration of a single amino acid, but there are also single or multiple deletions or duplications of mitochondrial genes that do not conform to maternal inheritance because they are caused by nuclear DNA defects. It is important to note that about 85 percent of the protein components of the respiratory chain are coded in nuclear DNA and are then imported into the mitochondrion; as mentioned above, this allows for a mitochondrial disease with a mendelian pattern of inheritance rather than a maternal one. Another of the general rules of mitochondrial inheritance is exemplified by an infantile myopathy (cytochrome oxidase deficiency) that is usually fatal but may also occur in a less severe form and have a later onset. In cases of earlier onset, there is less of the normal mitochondrial DNA than in the cases of later onset.

Since the unique function of mitochondria is the production of ATP by oxidative phosphorylation, it is not surprising that many of the genes contained in mitochondria code for proteins in the respiratory chain. However, there is not always concordance between the error in the mitochondrial genome and the enzymatic defect that leads to disease. Of the five complexes that make up the respiratory chain, cytochrome-c oxidase (complex IV) is the one most often disordered, and its deficient function gives rise to lactic acidosis, a feature common to many of the mitochondrial disorders (see further on). In keeping with the mutable nature of this class of disorders, it is thought that some cases of complex IV defect are autosomally transmitted. Complex I defects, which originate in mitochondrial mutations, are seen, for example, in Leber optic atrophy (page 949). A more complete account of the disorders of the mitochondrial respiratory chain can be found in the review by Leonard and Schapira.

As one would expect, aberrant function of the ubiquitous energy-producing mitochondria results in disease of many organs besides skeletal muscle (e.g., diabetes and other endocrinopathies and minor dysmorphic features are seen in several mitochondrial disorders). Nevertheless, most of the mitochondrial disorders affect the nervous system prominently and at times exclusively. Two characteristics traceable to mitochondrial abnormalities are particularly common; one is a special change in muscle fibers termed
ragged red fibers, actually a clumping of mitochondria in muscle fibers, and the other is a systemic lactic acidosis. Other than these, each of the mitochondrial diseases has distinctive features and in their central elements they do not resemble each other. The main syndromes are so-called MELAS and MERRF (acronyms defined further on), Leber hereditary optic atrophy, progressive external ophthalmoplegia, and the Leigh syndrome. These diseases are described in detail in the last part of this chapter.

Diagnostic Features of Hereditary Metabolic Diseases

In clinical practice, one should consider the possibility of a hereditary metabolic disease when presented with the following lines of evidence:

1. A neurologic disorder of similar type in a sibling or close relative
2. Recurrent nonconvulsive episodes of impaired consciousness
3. Some combination of unexplained symmetrical or generalized spastic weakness, cerebellar ataxia, extrapyramidal disorder, deafness, or blindness
4. Progression of a neurologic disease measured in weeks, months, or a few years
5. Mental retardation in a sibling or close relative
6. Mental retardation in an individual, particularly if there are no congenital somatic abnormalities
7. Intractable seizures in infants or young children
8. Infantile spasms and progressive myoclonic seizures with microcephaly in the absence of neonatal hypoxia-ischemia

In the face of such clinical information, one should obtain appropriate biochemical analyses of blood, urine, and cerebrospinal fluid (CSF); magnetic resonance imaging (MRI) of the brain; and, in certain instances, chromosome-genetic studies.

In addition to the investigation of symptomatic individuals, the array of available genetic and biochemical tests has made practical the mass screening of newborns for inborn metabolic defects. Innovative tests have also led to the discovery of a number of previously unknown diseases and have clarified the basic biochemistry of old ones. As a consequence, the neurologist’s role is changing. No longer must he wait until a disease of the nervous system has declared itself by conventional symptoms and signs, by which time the underlying lesion may have become irreversible. Now it is possible to find patients who, though asymptomatic, are at risk and to introduce dietary and other measures that may prevent injury to the nervous system. This is especially important to families who have already had an affected infant. To assume this new responsibility intelligently requires some knowledge of genetics, biochemical screening methods, and public health measures.

The many clinical syndromes by which these inborn errors of metabolism declare themselves vary in accordance with the nature of the biochemical defect and the stage of maturation of the nervous system at which these metabolic alterations become apparent. In phenylketonuria, for example, there is a specific effect on the cerebral white matter, mainly during the period of active myelination; once the stages of myelogenesis are complete, the biochemical abnormality becomes relatively harmless. Even more important from the neurologist’s point of view is the level of function that has been achieved by the developing nervous system when the disease strikes. A derangement of function in a neonate or infant, in whom much of the cerebrum is not fully developed, is much less obvious than one in an older child. Moreover, as the disease evolves, the clinical manifestations are always influenced by the ongoing maturation of the untouched elements in the nervous system. These interactions may give the impression of regression of attained neurologic function, lack of progress of development (developmental delay), or even improvement in function that is attributable to continuing maturation of the normal parts of the nervous system. The separation of metabolic-genetic from degenerative diseases (accorded a separate chapter) may disquiet the reader, for there are many overlaps between the two groups. The current division is tenable only until such time as all the degenerative diseases will have been shown to have a comprehensible pathogenesis.

Because of the overriding importance of the age factor and the tendency of certain pathologic processes to appear in particular epochs of life, it has seemed to the authors logical to group the inherited metabolic diseases not according to their major syndromes of expression, as we have done in other parts of the book, but in relation to the periods of life at which they are most likely to be encountered: the neonatal period, infancy (1 to 12 months), early childhood (1 to 4 years), late childhood, adolescence, and adult life. Only in the last two age periods do we return to the more clinically useful syndromic ordering of diseases.

In adopting this chronological subdivision, we realize that certain hereditary metabolic defects that most typically manifest themselves at a particular period in life are not necessarily confined to that epoch and may appear, sometimes in variant form, at a later stage. Such variations are noted at appropriate points in the discussion.

THE METABOLIC DISEASES OF THE NEONATAL PERIOD

A small number of progressive metabolic diseases become evident in the first few days of life. The importance of these diseases relates not to their frequency (they constitute only a small fraction of diseases that compromise nervous system function in the neonate) but to the fact that they must be recognized promptly if the infant is to be prevented from dying or from suffering a lifelong severe mental deficiency. This inherent threat introduces an element of urgency into neonatal neurology. Recognition of these diseases is also important for purposes of family and prenatal testing.

Two approaches to the neonatal metabolic disorders are possible—one, to screen every newborn, using a battery of biochemical tests of blood and urine, and the other, to undertake in the days following birth a detailed neurologic assessment that will detect the earliest signs of these diseases. Unfortunately, not all the biochemical tests have been simplified to the point where they can be adapted to a mass screening program, and many of the commonly used clinical tests at this age have yet to be validated as markers of disease. Moreover, many of the biochemical tests are costly, and practical issues such as cost-effectiveness insinuate themselves, to the distress of the pediatrician. The recent introduction of tandem mass spectrometry for the evaluation of blood and urine has allayed some of the latter concerns.

The Neurologic Assessment of Neonates with Metabolic Disease

As pointed out in Chap. 28, the neonate’s nervous system functions essentially at a brainstem-spinal level. The pallidum and visuo-
motor cortices are only beginning to be myelinated and their contribution to the totality of neonatal behavior cannot be very great. Neurologic examination, to be informative, must therefore be directed to evaluating diencephalic-midbrain, cerebellar—lower brainstem, and spinal functions. The integrity of these functions in the neonate is most reliably assessed by noting the following, again as described in Chap. 28:

1. Control of respiration and body temperature; regulation of thirst, fluid balance, and appetite—hypothalamus-brainstem mechanisms
2. Certain elemental automatisms, such as sucking, rooting, swallowing, grasping—brainstem-cerebellar mechanisms
3. Movements and postures of the neck, trunk, and limbs, such as reactions of support, extension of the neck and trunk, flexion movements and steppage—lower brainstem (reticulospinal), cerebellar, and spinal mechanisms
4. Muscle tone of limbs and trunk—spinal neuronal and neuromuscular function
5. Reflex eye movements—segmental midbrain and pontine mechanisms (a modified optokinetic nystagmus can be recognized by the third day of life)
6. The state of alertness and attention (stimulus responsivity and capacity of the examiner to make contact) as well as sleep-waking and electroencephalographic patterns—mesencephalic-diencephalic mechanisms
7. Certain reflexive reactions such as the startle (Moro) response and placing reactions of the foot and hand—upper brainstem—spinal mechanisms with possible cortical facilitation

Derangements of these functions are manifest as impairments of alertness and arousal, hypotonia, disturbances of ocular movement (oscillations of the eyes, nystagmus, loss of tonic conjugate deviation of the eyes in response to vestibular stimulation, i.e., to rotation of the upright infant), failure to feed, tremors, clonic jerkings, tonic spasms, opisthotonus, diminution or absence of limb movements, irregular or chaotic breathing, hypothermia or poikilothermia, bradycardia, circulatory difficulties, poor color, and seizures.

In most instances of neonatal metabolic disease, the pregnancy and delivery proceed without mishap. Birth at full term is usual. The infant is of a size and weight expected for the duration of pregnancy, and there are no signs of a developmental abnormality (in a few instances the infant is somewhat small, and in GM1 gangliosidosis there may be a pseudo-Hurler appearance; see further on). Furthermore, function continues to be normal in the first few days of life. The first hint of trouble may be the occurrence of feeding difficulties: food intolerance, diarrhea, and vomiting. The infant becomes fretful and fails to gain weight and thrive—all of which should suggest a disorder of amino acid, ammonia, or organic acid metabolism.

The first definite indication of disordered nervous system function is likely to be the occurrence of seizures. These usually take the form of unpatterned clonic or tonic contractions of one side of the body or independent bilateral contractions, sudden arrest of respiration, turning of the head and eyes to one side, or twitching of the hands and face. Some of the ill-formed seizures may become generalized. They occur singly or in clusters, and in the latter instance are associated with unresponsiveness, immobility, and arrest of respiration.

The other clinical abnormalities in the motor realm, according to authorities such as Prechtl and Beintema, can be subdivided roughly into three groups, each of which constitutes a kind of syndrome: (1) hyperkinetic-hypertonic, (2) apathetic-hypotonic, or (3) unilateral or hemisyndrome. Prechtl and Beintema, from a study of more than 1500 newborns, found that if clinical examination consistently discloses any one of the three syndromes, the chances are two out of three that by the seventh year the child will be manifestly abnormal neurologically. They found also that certain neurologic signs—such as facial palsy, lack of grasping, excessive flappiness, and impairment of sucking—while sometimes indicative of serious disease of the nervous system, are less dependable; also, being rare, these signs will identify but few brain-damaged infants. It is not the single neurologic sign but groups of them that are held to be the most reliable indices of brain abnormality, and the three syndromes mentioned above are the important ones, even though their anatomic and physiologic bases are not completely known.

In our observations of the neonatal metabolic diseases, we have endeavored to determine whether particular ones consistently manifest themselves by one or another of the three syndromes. We are able to affirm this to some degree. In cases of hypocalcemia-hypomagnesemia, the hyperkinetic-hypertonic syndrome prevails. Although most of the other diseases tend to induce the apathetic-hypotonic state, the hyperactive-hypertonic syndrome may represent the initial phase of the illness and always carries a less ominous prognosis than the apathetic-hypotonic state, which represents a more severe condition regardless of cause. We have been least confident in the recognition of the third putative group of unilateral abnormalities in the metabolic diseases. Even more discouraging has been the frequent overlapping of the two other syndromes and the fact that seizures may occur in all of them. The anatomic correlate for some of these neurologic abnormalities can be observed by MRI. Clearly what is needed is a more definitive neonatal neurologic semiology utilizing numerous stimulus-response tests, including those described by A. Thomas and Dargassis, supplemented by evoked potentials; also needed are ways of accurately quantifying more of the natural activities of this age period. Even the brain death syndrome, in which all brainstem-spinal reflexes are abolished, has not been fully defined in the neonate (Adams et al).

The Neonatal Metabolic Diseases and Their Estimated Frequency

In New England, screening of all newborns for metabolic disorders has been in operation for almost 50 years. Current data on the diseases with neurologic implications have been collated by our colleague, H. L. Levy of Children’s Hospital, Boston, and are summarized in Table 37-1. Some of these disorders can be recognized by simple color reactions in the urine; these are listed in Table 37-2.

To this group should be added the inherited hyperammonemetic syndromes and vitamin-responsive aminoacidopathies (such as pyridoxine dependency and biotinidase deficiency) as well as certain nonfamilial metabolic disorders that make their appearance in the neonatal period—hypocalcemia, hypothyroidism and cretinism, hypomagnesemia with tetany, and hypoglycemia.

It is important to note that the three most frequently identified hereditary metabolic diseases—phenylketonuria (PKU), hyperphenylalaninemia, and congenital hypothyroidism—do not be-
come clinically manifest in the neonatal period and are therefore discussed in a later portion of this chapter and in Chap. 40 (in the discussion of congenital hypothyroidism). This is fortunate, for it allows time to introduce preventive measures before the first symptoms appear. A number of others, which can be recognized either by screening or by early signs, are synopsized below.

Vitamin-Responsive Aminoacidopathies Included under this heading is a group of diseases that respond not to dietary restriction of a specific amino acid but to the oral supplementation of a specific vitamin. Some 30 vitamin-responsive aminoacidopathies are known (they are all rare, but the more frequent ones are listed in Table 41-3, on page 1000), and many of them result in injury to the central nervous system (CNS).

Pyridoxine-dependent aminoacidopathy Pyridoxine dependency is the classic example. This is a rare disease, inherited as an autosomal recessive trait. It is characterized by the early onset of convulsions, sometimes occurring in utero; failure to thrive; hypertonia-hyperkinesia; irritability; tremulous movements (“jittery baby”); exaggerated auditory startle (hyperacusis); and later, if untreated, by psychomotor retardation. The specific laboratory abnormality is an increased excretion of xanthurenic acid in response to a tryptophan load. There are decreased levels of pyridoxal-5-phosphate and gamma-aminobutyric acid (GABA) in brain tissue.

The neuropathology has been studied in only a few cases. One of our patients, a 13 1/2-year-old boy affected in the neonatal period, was left in a state of mental retardation, with pale optic discs and spastic legs; the brain weight was 350 g below normal. There was a decreased amount of central white matter in the cerebral hemispheres and a depletion of neurons in the thalamic nuclei and cerebellum, with gliosis (Lott et al). Most importantly, in pyridoxine deficiency, the administration of 50 to 100 mg of vitamin B₆ suppresses the seizure state, and daily doses of 40 mg permit normal development.

Biopterin Deficiency Some patients with increased concentrations of serum phenylalanine in the neonatal period are unresponsive to measures that lower phenylalanine. They are usually found to have a defect in biopterin metabolism. If this condition is unrecognized and not treated promptly, it leads to seizures of both myoclonic and later grand mal types combined with a poor level of responsiveness and generalized hypotonia. Swallowing difficulty is another prominent symptom. Within a few months, developmental delay becomes prominent. Unlike in PKU, phenylalanine

* Diaminophenylhydrazine.
hydroxylase enzyme levels are normal, but there is a lack of tetrahydrobiopterin, which is a cofactor of phenylalanine hydroxylase. Treatment consists of administration of tetrahydrobiopterin in a dosage of 7.5 mg/kg per day in combination with a low-phenylalanine diet. It is important to recognize this condition early in life by the measurement of urine pterins and to institute appropriate therapy before irreversible brain injury occurs.

**Galactosemia**  Inheritance of this disorder is autosomal recessive. The biochemical abnormality consists of a defect in galactose-1-phosphate uridyl transferase (GALT), the enzyme that catalyzes the conversion of galactose-1-phosphate to uridine diphosphate galactose. Several forms of galactosemia have been described, based on the degree of completeness of the metabolic block. In the classic (severe) form, the onset of symptoms is in the first days of life, after the ingestion of milk; vomiting and diarrhea are followed by a failure to thrive. Drowsiness, inattention, hypotonia, and diminution in the vigor of neonatal automatism then become evident. The fontanel may bulge, the liver and spleen enlarge, the skin becomes yellow (in excess of the common neonatal jaundice), and anemia develops. Rarely there is thrombocytopenia with cerebral bleeding. Cataracts may form due to the accumulation of galactitol in the lens. Studies of the outcome of surviving infants have shown retarded psychomotor development (IQ about 85), visual impairment, osteoporosis, ovarian failure, and residual cirrhosis, sometimes with splenomegaly and ascites. This seems to happen even with treatment. However, it is not known whether, in such patients, the treatment is always maintained through a critical developmental period. In one such patient, who died at 8 years, the main change in the brain was slight microcephaly with fibrous gliosis of the white matter and some loss of Purkinje and granule cells in the cerebellum, and also gliosis (Crome). The diagnostic laboratory findings are an elevated blood galactose level, low glucose, galactosuria, and deficiency of GALT in red and white blood cells and in liver cells. The treatment is essentially dietary, using milk substitutes; if this is instituted early, the brain should be protected from injury.

A late-onset neurologic syndrome has also been observed by Friedman and colleagues in galactosemic patients who survived the infantile disease. By late adolescence, they are found to be subnormal intellectually and socially maladjusted; some have shown cerebellar ataxia, dystonia, and apraxia. One of these patients was middle-aged.

**Organic Acidurias of Infancy**  These have been divided into ketotic and nonketotic types. Among the ketotic types, the main one is **propionic acidemia**. This is an autosomal recessive disease due to a primary defect in organic acid metabolism that is expressed clinically by episodes of vomiting, lethargy, coma, convulsions, hypertonia, and respiratory difficulty. The onset is in the neonatal or early infantile period; in time, psychomotor retardation becomes evident. Death usually occurs within a few months despite dietary treatment. Propionic acid, glycine, various forms of fatty acids, and butanone are elevated in the serum. As with other ketotic organic acidurias, high protein intake induces ketotic attacks. Marked restriction of dietary protein (specifically leucine) may prevent attacks of ketoacidosis and permit relatively good psychomotor development.

A number of other ketotic acidurias also occur in infancy. The most important of these are **methylmalonic acidemia**, **isovaleric acidemia**, **beta-keto acidemia**, and **lactic acidemia**. Each of these disorders can present with profound metabolic acidosis and intermittent lethargy, vomiting, tachypnea, tremors, twitching, convulsions, and coma, with early death in about half the patients and developmental retardation in those who survive. Rare subtypes of methylmalonic acidemia respond to vitamin B12. Isovaleric acidemia is characterized by a striking odor of stale perspiration, which has given it the sobriquet “sweaty foot syndrome.” Numerous metabolic defects, most commonly of pyruvate decarboxylase and pyruvate dehydrogenase, are responsible for the accumulation of lactic and pyruvic acids. The enzymatic defect of isovaleric acidemia has also been demonstrated in a recurrent form of episodic cerebellar ataxia and athetosis and in a persistent form in mitochondrial encephalopathies (Leigh disease), as described further on in this chapter.

A separate and rare deficiency of aromatic L-amino acid dehydrogenase has been described; the chemical signature is of low levels of almost all catecholamines. This defect is associated with a peculiar movement disorder of oculogyric crises, dystonia and athetosis and autonomic failure (see Swoboda et al).

A type II glutaric acidemia has also been observed in the neonatal period and causes episodes of acidosis with vomiting and hyperglycemia. Multiple congenital anomalies of brain and somatic structures and cardiomyopathy are conjoined. A diet low in the specific toxic amino acid and supplements of carnitine and riboflavin are recommended, but the effects are unclear.

In the *nonketotic form of hyperglycinemia*, there are high levels of glycine but no acidosis. The notable diagnostic finding is an elevation of the CSF glycine, several times higher than that of the blood. The effects on the nervous system are more devastating than in the ketotic form. In reported cases (the authors and our colleagues have seen several), the neonate is hypotonic, listless, and dyspneic, with dysconjugate eye movements, opisthotonic posturing, myoclonus, and seizures. A few such neonates survive to infancy but are extremely retarded and helpless. Spongy degeneration of the brain has been reported both in this disease and in the ketotic form (Shuman et al). No treatment has been effective in severe cases. In an atypical milder form, with neurologic abnormalities that appear in later infancy or childhood, reduction of dietary protein and administration of sodium benzoate in doses up to 250 mg/kg per day have been beneficial. The use of dextromethorphan, which blocks glycine receptors, is said to be effective in preventing seizures and coma.

**Inherited Hyperammonemias**  These are a group of six diseases caused by inborn deficiencies of the enzymes of the Krebs-Henseleit urea cycle; they are designated as *N*-acetyl glutamate synthetase, carbamyl phosphate synthetase (CPS), ornithine transcarbamylase (OTC), argininosuccinic acid synthetase (citrullinemia), argininosuccinase deficiency, and arginase deficiency. Hyperornithinemia-hyperammonemia-homocitrullinemia (HHH) and intrinsic protein intolerance are closely related disorders. They are identified by the finding of a persistent or episodic elevation of ammonia levels in the blood. A detailed account of these inherited hyperammonemic syndromes is contained in the review by Brusilow and Horwich.

The pattern of inheritance of each of these disorders is autosomal recessive except for OTC deficiency, which is X-linked dominant. Their clinical manifestations are a common expression of an accumulation of ammonia or of urea cycle intermediates in the brain; they differ only in severity, in accordance with the degree of completeness of the enzymatic deficiency and with the age of
the affected individual. The one exception is arginase deficiency, which commonly presents during later childhood as a progressive spastic paraplegia with mental retardation. Clinically it has been convenient to divide the hyperammonemias into two groups—one that presents in the neonatal period and another that presents in the weeks or months thereafter. This division is somewhat artificial, the clinical presentation being more in the nature of a continuous spectrum governed by the biologic factors mentioned above and even extending to rare cases that have their first symptoms during adulthood.

In the most severe forms of the hyperammonemic disorders, the infants are asymptomatic at birth and during the first day or two of life, after which they refuse their feedings, vomit, and rapidly become inactive and lethargic, soon lapsing into an irreversible coma. Profuse sweating, focal or generalized seizures, rigidity with opisthotonos, and hypothermia and hyperventilation have been observed in the course of the illness. These symptoms constitute a medical emergency, but even with measures to reduce serum ammonia, the disease is usually fatal.

In less severely affected infants, hyperammonemia develops some months later, when protein feeding is increased. There is a failure to thrive, and attempts to enforce feeding or during periods of constipation (both of which increase ammonia production in the bowel) there may be bouts of vomiting, lethargy, hyperirritability, and screaming. Respiratory alkalosis is a consistent feature. Other manifestations are periods of alternating hypotonia and hypertonia, seizures, ataxia, blurred vision, and of confusion, stupor, and coma. During episodes of stupor, often precipitated by dehydration, an alimentary protein load, or minor surgery, brain edema may be seen by computed tomography (CT) and MRI; with repeated relapses, the brain edema gives way to atrophy, which appears as symmetrical areas of decreased attenuation in the cerebral white matter. Between attacks, some patients with partial deficiency may be normal or show only a slight hyperbilirubinemia (diMaggio et al, Rowe et al). With decompensation, the bilirubin rises, as does ammonia, but neither reaches exceedingly high levels. After repeated attacks, signs of developmental delay with motor and mental retardation become evident, and the patient is vulnerable to recurrent infections. Two adult male patients in our care, who were married (but with azoospermia, which is common) and working at technically demanding jobs, came to medical attention because of bouts of visual blurring followed by stupor that evolved over hours (Shih et al). They had displayed an aversion to protein and milk products as children; in later life, after meals high in protein, they became encephalopathic, one with severe brain swelling. There are few phenotypic differences among the late-onset hyperammonemias except for argininosuccinic aciduria, in which excessive dryness and brittleness of the hair (trichorrhexis nodosa) are notable features, and the aforementioned arginase deficiency with spastic diplegia.

Diagnosis is established by the finding of hyperammonemia, often as high as 1500 mg/dL. The precise biochemical diagnosis requires testing of blood and urine for amino acids or assays for specific enzymes in red cells, liver, or jejunal biopsies. The primary hyperammonemias must be distinguished from the organic acidurias, including methylmalonic aciduria (see above), in which hyperammonemia can occur as a secondary metabolic abnormality.

In all the neonatal hyperammonemic diseases, the liver is often enlarged and liver cells appear to be inadequate in their metabolic functions, but how the enzymatic deficiencies or other disorders of amino acid metabolism affect the brain remains uncertain. It must be assumed that in some the saturation of the brain by ammonia impairs the oxidative metabolism of cerebral neurons, and when blood levels of ammonium increase (from protein ingestion, constipation, etc.), episodic coma or a more chronic impairment of cerebral functions occurs—as it does in adults with cirrhosis of the liver and portal-systemic encephalopathy. In the acutely fatal cases the brain is swollen and edematous and the astrocytes are diffusely increased in number and enlarged. The neurons are normal. Astrocytic swelling has been attributed to the accumulation of glutamate secondary to a suppression of glutamate synthetase. These changes have been reproduced in animals by the injection of ammonium chloride. When the hyperammonemia is abrupt in onset and severe, the resulting combination of encephalopathy, brain swelling, and respiratory alkalosis simulates the postinfectious Reye syndrome (page 969).

As in all forms of liver disease, valproic acid and other hepatic toxins may cause hepatic coma by further impairing the urea cycle enzymes. Notable are a few cases of inherited hyperammonemia that come to light in childhood or adulthood only after the administration of one of these drugs.

**Ornithine Transcarbamylase Deficiency and Argininosuccinic Aciduria** These are episodic diseases in which hyperammonemia develops usually later in childhood, but they may become manifest in the neonatal period. The main clinical features are episodic stupor, ataxia, and seizures. Their other features have been mentioned above.

**Treatment of the Hyperammonemic Syndromes** The treatment of acute hyperammonemic syndromes is directed to the lowering of ammonia levels by hemodialysis, exchange transfusions, and administration of arginine and certain organic acids. With subsidence of the acute symptoms, a systematic form of management should be undertaken, as outlined by Brusilow et al and by Msall et al. Sodium benzoate should be given in doses up to 250 mg/day, supplemented by sodium phenylacetate or sodium phenylbutyrate, which on theoretical grounds should divert nitrogen from the ureagenesis cycle. Arginine (50 to 150 mg/kg) should be added to the diet, since a deficiency of this substance may be responsible for the mental retardation and skin rashes. In more chronic cases, treatment consists of decreasing the ammonium load by the use of dietary protein restriction and by administration of oral antibiotics and lactulose. In infants with inborn errors of ureagenesis, there is a constant danger of recurrent episodes of hyperammonemia and coma, particularly in response to infections. In a few instances, careful management of the metabolic error has resulted in normal psychomotor development.

Liver transplantation may prove to be a therapeutic option.

**Branched-Chain Aminoacidopathies (Maple Syrup Urine Disease)** These conditions are caused by a deficiency of α-keto acid dehydrogenase, resulting in the accumulation of the branched-chain amino acids leucine, isoleucine, and valine and the corresponding branched-chain α-keto acids. Maple syrup urine disease may be taken as the prototype. The pattern of inheritance is autosomal recessive. With the most severe neonatal type, the infant appears normal at birth, but toward the end of the first week, poor feeding, intermittent hypertonicity, opisthotonos, and respiratory irregularities appear. These are followed by diminished neonatal automatism, convulsions, severe ketoacidosis, and often coma and death toward the end of the second to fourth week. This disease is one of the causes of the malignant epileptic syndrome of early infancy (Brett). Four milder forms of the disease have been de-
scribed. In these more chronic forms, feeding difficulties begin somewhat later in the early infantile period. They are manifest as recurrent infections, episodic acidosis, coma, and retarded growth and psychomotor development. Some of these patients, toward the end of the first year, may become quadriparetic or ataxic; or there may be only a nonspecific mental retardation. The disease derives its name from the maple syrup odor of the child’s urine which tests positively for 2,4-dinitrophenylhydrazine (DNPH).

Other important laboratory findings are increased plasma and urine concentrations of leucine, isoleucine, valine, and keto acids. Secondary accumulation of a derivative of α-hydroxybutyric acid probably accounts for the maple syrup odor. The neuropathologic findings are uncertain. In the first acute case described, only interstitial edema was observed; but in more chronic cases, pallor and loss of myelin and gliosis of parts of the cerebral white matter that myelinate after birth may be found. This can be visualized in CT and MRI scans.

Treatment by restriction of foods containing branched-chain amino acids (leucine, isoleucine, and valine) allows reasonably normal mental development, but only if such restriction is begun in the neonatal period and maintained lifelong. A thiamine-responsive variant with a slightly different pattern of keto acids described by Prensky and Moser responds variably to 30 to 300 mg of thiamine per day. The acute episodes, which threaten life, may require peritoneal dialysis to remove the putative toxic metabolites; they respond to the administration of glucose amino acid mixtures that are free of branched-chain keto acids.

Other Organic Acidemias In addition to maple syrup urine disease, there are a number of other metabolic disturbances, some of them of mitochondrial origin, that appear in the neonatal period or later and are marked by an organic acidemia. If they are severe, the infant develops a metabolic (lactic) acidosis soon after birth, with lethargy, feeding problems, rapid respirations, and vomiting. Or there may be irritability, jerky limb movements, and hypertonia. Later presentations take the form of feeding difficulties, repeated vomiting, hypotonia, and failure to thrive. With the passage of time, psychomotor retardation and drug-resistant seizures become evident. Metabolic stress—e.g., intercurrent infection or surgical procedures—may precipitate an episode of lactic or ketoacidosis.

Biochemical studies may disclose a biotinidase deficiency, methylmalonic aciduria, glutaric acidemia, methylglutaconic acidemia, or any number of other organic acid abnormalities. The precise abnormality is determined by measuring enzyme activity in white blood cells or cultured skin fibroblasts. As remarked above, some of these enzymes act in conjunction with a specific vitamin cofactor, so that exact diagnosis is imperative. The biotinidase deficiency may respond to 10 mg of biotin per day; the methylmalonic acidemia to 1 to 2 mg of vitamin B₁₂ per day; maple syrup urine disease to 10 to 20 mg of thiamine per day; and glutaric acidemia types I and II to 300 mg of riboflavin per day. The administration of carnitine may increase the elimination of toxic metabolites.

The care of these patients during an acute illness is of extreme importance. See Lyon and colleagues for a more complete description.

Sulfite Oxidase Deficiency with or without Molybdenum Cofactor Deficiency (See also page 804) These are extremely rare autosomal recessive disorders of sulfur metabolism, manifest clinically during the neonatal period by seizures, axial hypotonia, reduced level of responsiveness, and spasms with opisthotonos. There may be added dislocation of lenses, blindness, coloboma, and enophthalmos in combination with severe mental retardation and dysmorphic facial features (widely spaced eyes, long face and philtrum, puffy cheeks). There are no differences between pure sulfite oxidase deficiency and that associated with molybdenum cofactor deficiency. With survival into infancy, episodic confusion and stupor give way to seizures, mental retardation, and ataxia. In one of our cases, described by Shih and colleagues, a stroke-like syndrome of hemiplegia and aphasia appeared during a relapse at the age of 4.5 years, and in a Belgian case, subluxation of the lenses and choreoathetosis appeared at 8 months of age.

The biochemical abnormality is the accumulation of sulfite and possibly sulfatase as a result of the enzyme deficiency. Shih and colleagues have identified sulfite, thiosulfite, and S-sulfocysteine in the urine. Cerebral atrophy with loss and destruction of white matter and gray matter (cerebral cortex, basal ganglia, and cerebellar nuclei) has been observed in one postmortem examination. Increasing the intake of molybdenum or lowering the dietary intake of sulfur amino acids are therapeutic possibilities, not yet fully evaluated.

Diagnosis of Neonatal Metabolic Diseases

An important clue, of course, is provided by the history of a neonatal disease or unexplained death earlier in the same sibship or in a male maternal relative. A history that protein foods are rejected by the infant, or even a history among relatives of a dislike of protein or feeding difficulties in infancy, should raise the suspicion of an inherited hyperammonemic disorder or an organic acidemia. Measurements of blood ammonia and lactate and of the urine for ketones and reducing substances are the key laboratory tests. A wide-spectrum screening program may disclose a biochemical abnormality; this is the optimal state of affairs, especially when this type of screening provides the information before symptoms appear.

A number of nonhereditary metabolic diseases must be distinguished from the hereditary ones in this period of life. Hypocalcemia is one of the most frequent causes of neonatal seizures; tetany, spasms, and tremulous movements are usually present. Its cause is unknown, but the disorder is easily corrected, with excellent prognosis. Symptomatic hypoglycemic reactions are frequent in neonates. Premature infants are the most susceptible. Seizures, tremulousness, and drowsiness occur with blood sugar levels of less than 30 mg/dL in the mature infant and less than 20 mg/dL in the premature. Maternal toxemia and diabetes mellitus also predispose to hypoglycemia. Other causes of hypoglycemia are adrenal insufficiency, galactosemia, an idiopathic pancreatic islet-cell hyperplasia, the treatable fatty-acid beta oxidation disorders, and a congenital deficiency of CSF glucose transport—causing persistent hypoglycorrhachia and refractory seizures unless blood glucose levels are kept high. The damaging effects of untreated hypoglycemia have been well documented by Koivisto and colleagues. Also now identified is a disorder of CSF serine transport causing failure to thrive, severe developmental disability with spasticity and intractable epilepsy. The diagnosis is made by measuring CSF amino acids; treatment is with high-dose oral serine. Cretinism and idiopathic hypercalcemia are other recognizable entities that appear during this age period.

Aicardi has described a neonatal myoclonic syndrome and
Ohtahara, a malignant neonatal seizure disorder. In some of the cases, the neonatal syndrome merged later with the West type of infantile spasm disorder and the Lennox-Gastaut syndrome. Some of the cases had developmental abnormalities of the cerebrum, and severe mental retardation was the outcome. In other cases of this type, a familial coincidence was a feature; a metabolic defect has been suspected in these cases but never proved.

The hereditary metabolic diseases must also be distinguished from a number of other catastrophic disorders that occur at or soon after birth, such as asphyxia, perinatal ventricular hemorrhage with the respiratory distress syndrome of hyaline membrane disease, other hypotensive-hypoxic states, erythroblastosis fetalis with kernalerurus, neonatal bacterial meningitis, meningoencephalitis (herpes simplex, cytomegalic inclusion disease, listeriosis, rubella, syphilis, and toxoplasmosis), and hemorrhagic disease of the newborn. These are described in Chap. 38, on the developmental diseases.

**THE HEREDITARY METABOLIC DISEASES OF INFANCY**

The hallmark of all the hereditary metabolic diseases is psychosensormotor regression. However, those that have their onset in the first year of life pose extraordinary problems in neurologic diagnosis. If the onset is in the first postnatal months, before the infant has had time to develop the normal complex repertoire of behavior, the first signs of disease may take the form of subtle delays in maturation rather than of psychomotor regression. Departures from normalcy include a lack of interest in the surroundings, a lack of visual engagement, poor head control, an inability to sit up at the usual time, poor hand-eye coordination, and persistence of infantile automatisms. Of course, embryologic maldevelopment of the brain may have similar effects, and systemic diseases and other visceral malformations—such as cystic fibrosis, renal disease, biliary atresia and congenital heart disease, chronic infection, malnutrition, and seizures (with drug therapy)—may appear to impede psychomotor development. Diagnosis becomes somewhat easier in the second half of the first year, especially if development in the first half had proceeded normally. Then an observant mother, usually one with older children, can perceive a loss of certain early acquisitions, attesting to the progressive nature of a disease.

The most distinctive members of this category of neurologic disease are the leukodystrophies and the so-called lysosomal storage diseases. The leukodystrophies are a group of inherited metabolic diseases of the nervous system characterized by progressive, symmetrical, and usually massive destruction of the white matter of the brain and sometimes of the spinal cord; each type of leukodystrophy is distinguished by a particular abnormal product of degeneration of myelinated fibers. In the lysosomal storage diseases, there is a genetic deficiency of the enzymes (usually one or more of the acid hydrolases) necessary for the degradation of specific glycosidic or of peptide linkages in the intracytoplasmic lysosomes, causing nerve cells to become engorged with material that they would ordinarily degrade. These metabolites eventually damage the nerve cell or its myelin sheath.

Most of these diseases are classified as sphingolipidoses. It was Brady in 1966 who made the observation that in each of these disorders an increased quantity of sphingolipid accumulated in the brain and other tissues. The sphingolipids are a class of intracellular lipids that all have ceramide as their basic structure, but each has a different attached oligosaccharide or phosphorylcholine. The rate of synthesis of the sphingolipids is normal and their accumulation results from a defect of a specific lysosomal enzyme that normally degrades each of the glycoproteins, glycolipids, and mucopolysaccharides by removing a monosaccharide or sulfate moiety. It is the type of enzyme deficiency and accumulated metabolite, as well as the tissue distribution of the undegradable substrate, that impart a distinctive biochemical and clinical character to each of the diseases in this category.

The concept of lysosomal storage diseases, introduced by Hers in 1965, excited great interest among neurologists at the time because it provided the potential for prenatal diagnosis and the detection of carriers. The diagnosis of this group of diseases has also been facilitated by the use of CT scanning, MRI, and evoked response techniques, which confirm the existence of leukodystrophies, and by the electron microscopic examination of skin, rectal, or conjunctival biopsies, circulating lymphocytes, and cultured amniotic fluid cells, which discloses the lysosomal storage material in nonneural cells. The activity of most lysosomal enzymes can be determined by exposing them to artificial chromogenic or fluorogenic substrates.

There are now more than 40 lysosomal storage diseases in which the biochemical abnormalities have been determined. They are listed in Table 37-3, which was adapted originally from the review of Kolodny and Cable and recently updated by our colleague E. Kolodny. In addition to the sphingolipidoses, which are the lysosomal storage diseases most likely to be encountered in the first year of life, the table includes the storage diseases that may not appear clinically until a later age (in childhood and adolescence)—to be considered later in this chapter. The frequency of each of the various types as detected in a comprehensive study of the Australian population is given by Meikle and colleagues and generally accords with the ordering below. A broad perspective on the frequency of the lysosomal disorders can be appreciated from the report of the Australian national referral laboratory. There were 545 cases (75 detected prenatally) over a 16-year period, a calculated frequency of 1 case per 7700 live births. This is close to the estimate in the United States, which is approximately 1 per 5000 births.

The more frequent types of lysosomal storage diseases are as follows:

1. Tay-Sachs disease (GM2 gangliosidosis) and variants such as Sandhoff disease
2. Infantile Gaucher disease
3. Infantile Niemann-Pick disease
4. Infantile GM2 generalized gangliosidosis
5. Krabbe globoid-body leukodystrophy
6. Farber lipogranulomatosis
7. Pelizaeus-Merzbacher and other sudanophilic leukodystrophies
8. Spongy degeneration (Canavan-van Bogaert-Bertrand disease)
9. Alexander disease
10. Zellweger encephalopathy
11. Lowe oculorenal-cerebral disease

In the following descriptions, we have summarized the clinical and pathologic features of each of the diseases listed above and have italicized the characteristic clinical signs and corroborative laboratory tests. Leigh disease, which may appear in this age group,

is described with the mitochondrial diseases, further on in this chapter.

Tay-Sachs Disease (GM₂ Gangliosidosis, Hexosaminidase A Deficiency)

This is an autosomal recessive disease, mostly of Jewish infants of eastern European (Ashkenazic) background. The first description came from Tay, a British ophthalmologist, in 1881, and Sachs, an American neurologist, in 1887; they called it amaurotic family idiocy. The disease becomes apparent in the first weeks and months of life, almost always by the fourth month. The first manifestations are a regression of motor activity and an abnormal startle to acoustic stimuli, accompanied by listlessness, irritability, and poor reactions to visual stimuli. These are followed by a progressive delay in psychomotor development or regression (by 4 to 6 months), with inability to roll over and sit. At first, axial hypotonia is prominent, but later spasticity and other corticospinal tract signs and visual failure become evident. Degeneration of the macular cells exposes the underlying red vascular choroid surrounded by a whitish gray ring of retinal cells distended with ganglioside. The resulting appearance is of the cherry-red spot with optic atrophy (Fig. 37-1). These are observed in the retinas in more than 90 percent of patients (but are also characteristics of other storage diseases—see Table 37-4). In the second year, there are tonic-clonic or minor motor seizures and an increasing size of the head and diastasis of sutures with relatively normal-sized ventricles; in the third year, the clinical picture is one of dementia, decerebration, and blindness. Cachexia becomes increasingly severe and death occurs at 2 to 4 years. The electroencephalogram (EEG) becomes abnormal in the early stages (paroxysmal slow waves with multiple spikes). Occasionally one can find basophilic granules in leukocytes and vacuoles in lymphocytes. There are no visceral, skeletal, or bone marrow abnormalities by light microscopy.

The basic enzymatic abnormality is a deficiency of hexosaminidase A, which normally cleaves the N-acetylgalactosamine from gangliosides. As a result of this deficiency, GM₂ ganglioside accumulates in the cerebral cortical neurons, Purkinje cells, retinal ganglion cells, and, to a lesser extent, larger neurons of the brainstem and spinal cord. The enzymatic defect can be found in the serum, white blood cells, and cultured fibroblasts from the skin or amniotic fluid, the latter giving parents the option of abortion to prevent a presently untreatable and fatal disease. Testing for hexosaminidase A also permits the detection of heterozygote carriers of the gene defect. Detection of this enzyme defect is complicated by the fact that more than 50 mutations of the alpha subunit of the beta hexosaminidases have been isolated and the enzyme itself is normal in one form of activator enzyme deficiency. Fortunately, only three mutations account for 98 percent of the form that is common in Jews.

The brain is large, sometimes twice the normal weight. In addition, there is a loss of neurons and a reactive gliosis; remaining nerve cells throughout the CNS are distended with glycolipid. Biopsies of the rectal mucosa disclose glycolipid distention of the ganglion cells of the Auerbach plexus, but the need for this procedure has been obviated by enzyme analysis of white blood cells. Under the electron microscope, the particles of stored material appear as membranous cytoplasmic bodies. Retinal ganglion cells are distended with the same material and, together with fat-filled histiocytes, cause the whitish gray rings around the fovea, where there are no nerve cells, as noted above.

The same neuropathologic process has been found in a few congenital cases in which there was a rapidly progressive decline of a microcephalic infant. Kolodny and Raghavan have described two other, probably allelic variants of the hexosamine A defect. One presents as a childhood spinoocerebellar degeneration, the other as a progressive spinal muscular atrophy in juveniles and young adults, due presumably to widespread involvement of spinal motor neurons (see further on).

Tay-Sachs disease is untreatable but can be prevented by testing all individuals of Jewish origin for the recessive trait. Since this screening was instituted at the E. K. Shriver Center in 1968 and adopted throughout the state, it is essentially unknown in Massachusetts.

In Sandhoff disease, which affects non-Jewish infants, there is a deficiency of both hexosaminidase A and B, moderate hepatosplenomegaly, and coarse granulations in bone marrow histiocytes. The clinical and pathologic picture is the same as in Tay-Sachs disease except for the additional signs of visceral lipid storage. Occasionally these visceral organs are not enlarged.

In recent years numerous variants of hexosaminidase A and B deficiency have been identified. They differ clinically from Tay-Sachs disease in having a later onset, less extensive brain involvement (cortical neurons relatively spared and intense affection of basal ganglia as well as cerebellar and spinal neurons). Accordingly, the clinical expression of the variants appearing in childhood,
adolescence, and adult life take the form of attherosclerosis, dystonia, ataxia, and motor neuron paralysis; mental function can be normal.

**Infantile Gaucher Disease (Type II Neuronopathic Form, Glucocerebrosidase Deficiency)**

This is an autosomal recessive disease without ethnic predominance, first described by Gaucher in 1882. The onset of the neuronopathic form is usually before 6 months and frequently before 3 months. The clinical course is more rapid than that of Tay-Sachs disease (most patients with infantile Gaucher disease do not survive beyond 1 year and 90 percent not beyond 2 years). Oculomotor apraxia and bilateral strabismus are early signs and are accompanied by rapid loss of head control, of ability to roll over and sit, and of purposeful movements of the limbs—along with apathy, irritability, frequent crying, and difficulty in sucking and swallowing. In some cases progression is slower, with acquisition of single words by the first year, bilateral corticospinal signs (Babinski signs and hyperactive tendon reflexes), persistent retroflexion of the neck, and strabismus. Laryngeal stridor and trismus, diminished reaction to stimuli, smallness of the head, rare seizures, normal optic fundi, enlarged spleen and slightly enlarged liver, poor nutrition, yellowish skin and scleral pigmentation, osteoporosis, vertebral collapse and kyphoscoliosis, and sometimes lymphadenopathy complete the clinical picture. The CSF is normal; the EEG is abnormal but nonspecifically so.

The important laboratory findings are an increase in serum acid phosphatase and characteristic histiocytes (Gaucher cells) in marrow smears and liver and spleen biopsies. A deficiency of glucocerebrosidase in leukocytes and hepatocytes is diagnostic; glucocerebroside accumulates in the involved tissues. The characteristic pathologic feature is the Gaucher cell, 20 to 60 μm in diameter, with a wrinkled appearance of the cytoplasm and eccentricity of the nucleus. These cells are found in the marrow, lungs, and other viscera; neuronal storage is seldom evident. In the brain, the main abnormality is a loss of nerve cells—particularly in the bulbar nuclei but also in the basal ganglia, cortex, and cerebellum—and a reactive gliosis that extends into the white matter.

In contrast to the type II form described above, type I Gaucher disease is a nonneuronopathic and relatively benign form. A less frequent type III Gaucher disease is neuronopathic. It expresses itself in late childhood or adolescence by a slowly progressive mental decline, seizures, and ataxia, and, later, by spastic weakness and splenomegaly. Vision and retinæ remain normal. Highly diagnostic is the defect in voluntary lateral gaze, with full movements on the oculocephalic ("doll’s-head") maneuver. These signs help to differentiate Gaucher from Niemann-Pick disease, in which vertical eye movements are lost (see below). The nucleotide sequence of the cloned glucocerebrosidase of type I Gaucher disease was found by Tsuji and associates to be different from that of types II and III. There is no treatment for the latter types.

**Infantile Niemann-Pick Disease (Sphingomyelinase Deficiency)**

This is also an autosomal recessive disease. Two-thirds of the affected infants have been of Ashkenazi Jewish parentage. The onset of symptoms in the usual type A disease is between 3 and 9 months of age, frequently beginning with marked enlargement of liver, spleen, and lymph nodes and infiltration of the lungs; rarely there is jaundice and ascites. Cerebral abnormalities are definite by the end of the first year, often earlier. The usual manifestations are loss of spontaneous movements, lack of interest in the environment, axial hypotonia with bilateral corticospinal signs, blindness and amaurotic nystagmus, and a macular cherry-red spot (in about one-quarter of the patients). Seizures may occur but are relatively late. There is no acoustic-induced startle or myoclonus, and head size is normal or slightly reduced. Loss of tendon reflexes and slowed conduction in peripheral nerves have been recorded but are rare. Protuberant eyes, mild hypertelorism, slight yellowish pigmentation of oral mucosa, and dysplasia of dental enamel have also been reported but are rare. Most patients succumb to an intercurrent infection by the end of the second year.

Vacuolated histiocytes ("foam cells") in the bone marrow and vacuolated blood lymphocytes are the important laboratory findings. A deficiency of sphingomyelinase in leukocytes, cultured fibroblasts, and hepatocytes is diagnostic. Pathologic examination reveals a decrease in the number of neurons; many of the remaining ones are pale and balloon and have a granular cytoplasm. The most prominent neuronal changes are seen in the midbrain, spinal cord, and cerebellum. The white matter is little affected. The retinal nerve cell changes are similar to those in the brain. The foamy histiocytes (Niemann-Pick cells) that fill the viscera contain sphingomyelin and cholesterol; the distended nerve cells contain mainly sphingomyelin.

There are also less severe late infantile and juvenile forms of Niemann-Pick disease types C and D. These are discussed in a later section of this chapter.

**Infantile Generalized GM₁ Gangliosidosis (Type I, β-Galactosidase Deficiency, Pseudo-Hurler Disease)**

This is probably an autosomal recessive disease without ethnic predominance. The infants appear abnormal at birth. They have dysmorphic facial features, like those of the mucopolysaccharidoses: depressed and wide nasal bridge, frontal bossing, hypertelorism, puffy eyelids, long upper lip, gingival and alveolar hypertrophy, macroglossia, and low-set ears. These features, with the bone changes mentioned below, account for the term pseudo-Hurler. Other indications of the disease are the onset of impaired awareness and reduced responsivity in the first days or weeks of life; lack of psychomotor development after 3 to 6 months; hypotonia, and later hypertonia with lively tendon reflexes and Babinski signs. Seizures are frequent. The head size is variable (microcephaly more often than macrocephaly). Loss of vision, coarse nystagmus and strabismus, macular cherry-red spots (in half the cases), flexion pseudo-contractures of elbows and knees, kyphoscoliosis, and enlarged liver and sometimes enlarged spleen are the other important clinical findings. Radiographic abnormalities include subperiosteal bone formation, midshaft widening and demineralization of long bones, and hypoplasia and beaking of the thoracolumbar vertebrae. Vacuoles are seen in 10 to 80 percent of blood lymphocytes and foam cells in the urinary sediment.

A partial or complete deficiency of β-galactosidase and accumulation of GM₁ ganglioside in the viscera and in neurons and glial cells throughout the CNS are the specific biochemical abnormalities. In addition, the epithelial cells of renal glomeruli, histiocytes of the spleen, and liver cells contain a modified keratan sulfate and a galactose-containing oligosaccharide. The changes in the bone are also like those in the Hurler form of mucopolysac-
A remarkably benign variant, also inherited as an autosomal recessive trait, begins later in childhood but may advance so slowly as to allow attainment of adult life. Dystonia, myoclonus, seizures, visual impairment, and macular red spots were features of the two cases described by Goldman and coworkers.

Globoid Cell Leukodystrophy (Krabbe Disease, Galactocerebrosidase Deficiency)

This is an autosomal recessive disease without ethnic predilection, first described by Krabbe, a Danish neurologist, in 1916. The onset is usually before the sixth month and often before the third month (10 percent after 1 year). Early manifestations are generalized rigidity, loss of head control, diminished alertness, frequent vomiting, irritability and bouts of inexplicable crying, and spasms induced by stimulation. With increasing muscular tone, opisthotonic recurvation of the neck and trunk develops. Later signs are adduction and extension of the legs, flexion of the arms, clenching of the fists, hyperactive tendon reflexes, and Babinski signs. Later still, the tendon reflexes are depressed or lost but Babinski signs remain, an indication that neuropathy is added to corticospinal damage. This finding, shared with some of the other leukodystrophies, is of diagnostic value. Blindness and optic atrophy supervene. Convulsions occur but are rare and difficult to distinguish from tonic spasms. Myoclonus in response to auditory stimuli is present in some cases. The head size is normal or, rarely, slightly increased. In the last stage of the disease, which may occur from one to several months after the onset, the child is blind and usually deaf, opisthotonic, irritable, and cachectic. Most patients die by the end of the first year and survival beyond 2 years is unusual, although a considerable number of cases of later onset have been reported (see below).

The EEG shows nonspecific slowing without spikes, and the CSF protein is usually elevated (70 to 450 mg/dL). CT scanning and MRI reveal symmetrical nonenhancing areas of increased density in the internal capsules and basal ganglia. As the disease advances, more of the cerebral white matter and brainstem become involved (Fig. 37-2). Neuropathy is a feature in most cases, but clinical signs may be difficult to detect except for a decrease or loss of tendon reflexes; however, there is electromyographic (EMG) evidence of denervation and slowed motor and sensory nerve conduction velocities, reflecting a demyelinating type of polyneuropathy.

The deficient lysosomal enzyme in Krabbe disease is galactocerebrosidase (also called galactosylceramide β-galactosidase, or GALT); it normally degrades galactocerebroside to ceramide and galactose. The deficiency results in the accumulation of galactocerebroside; a toxic metabolite, psychosine, leads to the early destruction of oligodendrocytes and depletion of lipids in the cerebral white matter. The globoid cell reaction, however, indicates that impaired catabolism of galactocerebroside is also important. Gross examination of the brain discloses a marked reduction in the cerebral white matter, which feels firm and rubbery. Microscopically, there is widespread myelin degeneration, absence of oligodendrocytes, and astrocytic gliosis in the cerebrum, brainstem, spinal cord, and nerves. The characteristic globoid cells are large histiocytes containing the accumulated metabolite. Schwann cells have tubular or crystalloid inclusions under electron microscopy.

Figure 37-2. Krabbe disease. T2-weighted MRI in the axial plane demonstrating an abnormal high signal in the periventricular white matter. Arcuate fibers are spared. The patient was a 14-month-old boy with severe generalized rigidity. Diagnosis was proved postmortem (4 months after the MRI). (Reproduced by permission from Lee SH, Rao K, Zimmerman RA: Cranial MRI and CT, 3rd ed. New York, McGraw-Hill, 1992.)

About a dozen variants of globoid cell leukodystrophy have been reported, many of them allowing survival for years. In these, neurologic regression begins in the 2- to 6-year period. Visual failure with optic atrophy and a normal electroretinogram is an early finding. Later there is ataxia as well as spastic weakness of the legs, mental regression, and finally decerebration. In three patients observed by R. D. Adams, a progressive quadriplegia with mild pseudobulbar signs, slowly progressive impairment of memory and other mental functions, dystonic posturing of the arms, and preserved sphincteric control constituted the clinical picture. The patients were alive at ages 9, 12, and 16 years. We have observed another rare variant, beginning in adult years, with spastic quadriplegia (asymmetrical) and optic atrophy. Mentation was essentially normal and, on CT scanning and MRI, the cerebral lesion was restricted. Unlike typical Krabbe disease, these CNS abnormalities are unaccompanied by any change in the spinal fluid. The nerve conduction velocities in the late-onset form may be either normal or abnormal.

Kolodny and colleagues have reported 15 cases of even later onset (ages 4 to 73 years); pes cavus, optic pallor, progressive spastic quadriplegia, a demyelinating sensorimotor neuropathy, and symmetrical parieto-occipital white matter changes (on imaging studies) were the main features. Galactocerebrosidase levels were not as much reduced as in the infantile form; possibly these late-onset variants represent a structural mutation of the enzyme (see Farrell and Swedberg).

In this disease, as well as others described in this chapter, it has become clear that different mutations involving the same enzyme or metabolic pathway can produce strikingly different phenotypes and that there is a wide range in the age of onset in what had been considered, until relatively recently, a disease confined to infancy and early childhood.
Lipogranulomatosis (Farber Disease, Ceramidase Deficiency)

This is a rare disorder that is probably genetic, affecting both sexes and without a particular racial predilection. The onset is in the first weeks of life, with a hoarse cry due to fixation of laryngeal cartilage, respiratory distress, and sensitivity of the joints, followed by characteristic periarticular and subcutaneous swellings and progressive arthropathy, leading finally to ankylosis. Usually there is severe psychomotor retardation, but a few patients have appeared neurologically normal. Inanition and recurrent infections lead to death in the first 2 years. The diagnostic abnormality is a deficiency of ceramidase, leading to accumulation of ceramide. There is widespread lipid storage in neurons, granulomas of the skin, and accumulation of periodic acid–Schiff (PAS)–positive macrophages in periarticular and visceral tissues.

Sudanophilic Leukodystrophies and Pelizaeus-Merzbacher Disease

These are a heterogeneous group of disorders that have in common a defective myelination of the cerebrum, brainstem, cerebellum, spinal cord, and peripheral nerves. Morphologic peculiarities and genetic features separate a certain group called Pelizaeus-Merzbacher disease; other types have been artificially delineated; as a result, a relatively meaningless terminology has been introduced.

Pelizaeus-Merzbacher Disease This is predominantly an X-linked disease of infancy, childhood, and adolescence and includes other closely related pathologic entities with different modes of inheritance. The affected gene encodes proteolipid protein (PLP), one of the two myelin basic proteins. Koeppen and associates have offered evidence of a defective synthesis of this protein. While one group of PLP mutations causes Pelizaeus-Merzbacher disease, another set causes an infantile spastic paraplegia.

The onset of symptoms is most often in the first months of life; other cases begin later in childhood. The first signs are abnormal movements of the eyes (rapid, irregular, often asymmetrical pendular nystagmus), jerk nystagmus on extremes of lateral movements, upbeat nystagmus on upward gaze, and hypometric saccades (Trobe et al). There is spastic weakness of the limbs, optic atrophy (often with unexplained retention of pupillary light reflex), ataxia of limb movement and intention tremor, choreiform or athetotic movements of the arms, and slow psychomotor development with delay in sitting, standing, and walking. Seizures occur occasionally. In later-developing cases, pendular nystagmus, choreoathetosis, corticospinal signs, dysarthria, cerebellar ataxia, and mental deterioration are the major manifestations. There are milder cases of later onset with behavioral peculiarities and loss of tendon reflexes and, rarely, pure spastic paraparesis.

CT scanning and MRI confirm the extensive and symmetrical white matter involvement. In the most severe cases, Seitelberger has observed an absence of oligodendrocytes and myelinated fibers. It is hypothesized that proteolipids accumulate in the endoplasmic reticulum of the oligodendrocytes, resulting in apoptosis. Patients may survive to the second and third decades. One group of cases resembles the Cockayne syndrome (page 824), with photosensitivity of skin, dwarfism, cerebellar ataxia, corticospinal signs, cataracts, retinitis pigmentosa, and deafness. Pathologically, islands of preserved myelin impart a tigroid pattern of degenerated and intact myelin in the cerebrum. Seitelberger has obtained pathologic verification of this lesion in cases beginning as late as adult years. This disease and Cockayne syndrome are the only leukodystrophies in which nystagmus has been an invariable finding.

Koeppen and Robitaille, in a current and thorough review of the subject, summarize the present-day understanding of the pathogenesis, based on misfolding of myelin proteins.

Unclassifiable Sporadic and Familial Sudanophilic Leukodystrophies There are two types of such disorder, one with early and the other with late onset. In the former, onset is before 3 months, with survival of less than 2 years; in the latter type, onset is from 3 to 7 years and the course is chronic. Psychomotor regression; spastic paralysis; incoordination; blindness and optic atrophy; seizures (rare); severe microcephaly; and absence of skeletal, visceral, and hematologic evidence of the metabolic abnormality are the main features. No characteristic laboratory abnormalities are known. Diffuse degeneration of myelinated fibers with phagocytosis of sudanophilic degeneration products of myelin (visible by MRI) and gliosis are the major changes. In two cases followed by R. D. Adams and T. Rabinowicz, a brother and sister living to adolescence, the destroyed white matter was widely cavitated.

Spongy Degeneration of Infancy (Canavan-van Bogaert-Bertrand or Canavan Disease)

This is an autosomal recessive disease described in 1931 by Canavan as a form of Schilder disease (see Chap. 36) but later categorized as a spongy degeneration of the brain by van Bogaert and Bertrand. Of 48 affected families reported by Banker and Victor, 28 were Jewish. Onset is early, usually recognizable in the first 3 months of life and sometimes in the first neonatal weeks. There is either a lack of development or rapid regression of psychomotor function, loss of sight and optic atrophy, lethargy, difficulty in sucking, irritability, reduced motor activity, hypotonia followed by spasticity of the limbs with corticospinal signs, and an enlarged head (macrocephaly). There are no visceral or skeletal abnormalities, but a variable sensorineural hearing loss has been found (Ishiyama et al). Seizures occur in some cases. An interesting but unexplored aspect of the disease is the occurrence of blond hair and light complexion in affected members, in contrast to the darker hair and complexion of their normal siblings (Banker and Victor).

The CSF is usually normal, but the protein is slightly elevated in some cases. The disease is characterized by an increased urinary excretion of N-acetyl-L-aspartic acid (NAA), which may be used as a biochemical marker. It reflects the basic enzyme abnormality, a deficiency of aminocyclose II, which catalyzes the breakdown of NAA (Matalon et al). On CT scans there is attenuation of cerebral and cerebellar white matter in an enlarged brain with relatively normal-sized ventricles. The MRI appearance (Fig. 37-3) is that of diffuse, somewhat uneven, high signal intensity on T2-weighted images. A leukodystrophy with behavioral regression, an enlarging head, a characteristic MRI abnormality, and a marked elevation of urinary NAA should leave little doubt about the diagnosis.

The characteristic pathologic changes are an increase in brain volume (and weight), spongy degeneration in the deep layers of the cerebral cortex and subcortical white matter, widespread depletion of myelin involving the convolutional more than the central white matter, loss of Purkinje cells, and hyperplasia of Alzheimer
type II astrocytes throughout the cerebral cortex and basal ganglia. Adachi and coworkers have demonstrated an abnormal vacuolar accumulation of fluid in astrocytes and between split myelin lamellae; they have suggested that the loss of myelin is secondary to these changes.

The enlargement of the brain in this disease must be distinguished clinically from GM2 gangliosidosis, Alexander disease, Krabbe disease, and nonprogressive megalencephaly and pathologically from a variety of disorders characterized by vacuolation of nervous tissue. There is no treatment.

Alexander Disease

This distinctive disease shares certain features with the leukodystrophies and also with gray matter diseases (poliodystrophies), both clinically and pathologically. The onset is in infancy with a failure to thrive, psychomotor retardation, spasticity of the craniospinal musculature, and seizures. An early and progressive macrocephaly has been a consistent feature. Alexander was the first to call attention to the enlargement of the brain, the extensive loss of cerebral white matter, and highly characteristic inclusions (the so-called Rosenthal fibers noted below) in astrocytes, and subpial and periventricular regions.

Pathologically, there are severe destructive changes in the cerebral white matter, most intense in the frontal lobes. Distinctive eosinophilic hyaline bodies, most prominent just below the pia and around blood vessels, are seen throughout the cerebral cortex, brainstem, and spinal cord. These have been identified as Rosenthal fibers and probably represent glial degradation products.

The astrocytic changes have been traced to a mutation in the glial fibrillary protein, according to Gorospe et al. This gene abnormality gives rise to the intermediate filament protein in astrocytes and, presumably, to the Rosenthal fiber inclusions. On the basis of this and related gene mutations, apparent milder forms of Alexander disease have been reported in juveniles and adults. They differed clinically in lacking the cerebral leukoencephalopathy. Instead, after a long period of constipation, sleep disorder, and orthostatic hypotension during adolescence, bulbar symptoms (dysarthria, dysphonia, and dysphagia), seizures, and in some cases ataxia gradually emerged during adult years. The myelin changes and atrophy of the medulla seen in MRI were confirmed by postmortem examination and the Rosenthal fibers; GFAP fibers were present in two autopsied cases.

Stumpf and colleagues advanced the idea that the glial and GFAP changes relate the cases in the large kindred they studied to a variant of Alexander disease.

Alpers Disease This is a progressive disease of the cerebral gray matter, known also as progressive cerebral poliodystrophy or diffuse cerebral degeneration in infancy. A familial form (probably autosomal recessive) as well as many sporadic cases have been reported. In both groups there is a certain uniformity of clinical features—loss of smile and disinterest in the surroundings, sweating attacks, seizures and diffuse myoclonic jerks beginning in early infancy and followed by incoordination of movements; progressive spasticity of limb, trunk, and cranial muscles; blindness and optic atrophy; growth retardation and increasing microcephaly; and finally virtual decortication. In some instances, the late onset of jaundice and fatty degeneration or cirrhosis of the liver have been described (Alpers-Huttenlocher syndrome); the hepatic changes are distinctive and probably not related to the use of anticonvulsant drugs, as had been hypothesized (Harding et al). By the age of 4 years, these patients are hypotonic, anemic, and thrombocopenic. They also show hair changes (trichorrhexis).

The nature of this combined hepatic-cerebral degeneration remains unexplained, but some instances have been connected to the mitochondrial disorders, as noted below. EEG abnormalities, progressive atrophy (particularly occipital) on the CT scan, loss of visual evoked potentials, and abnormal liver function tests are diagnostically useful. Neuropathologic examination shows marked atrophy of the cerebral convolutions and cerebellar cortex, with loss of nerve cells and fibrous glia (“walnut brain”). The cerebral white matter and basal ganglia are relatively preserved. In some cases, the spongiform vacuolization of the gray matter of the brain resembles that seen in Creutzfeldt-Jakob disease. Hypoglycemic, hypoxic, and hypertensive encephalopathies must always be considered in the diagnosis but can usually be eliminated by knowledge of the clinical circumstances at the onset of the illness.

A number of biochemical abnormalities have been identified in patients with Alpers disease, including pyruvate dehydrogenase deficiency, decreased pyruvate utilization, dysfunction of the citric acid cycle, and decreased cytochromes a and a3. The biochemical and pathologic changes suggest a relationship to Leigh encephalomyelopathy and a mitochondrial transmission. Many authoritative texts classify it with the mitochondrial diseases, but its nosologic status is in our opinion still uncertain (see Shaffner and Wallace).

Congenital Lactic Acidosis

This uncommon disease of the neonatal period or early infancy has many biochemical etiologies. The symptoms have consisted of psychomotor regression and episodic hyperventilation, hypotonia, and
convulsions, with intervening periods of normalcy. Choreoathetosis has been observed in a few cases. Death often occurs before the third year. The important laboratory findings are acidosis with an anion gap and high serum lactate levels and hyperalaninemia. Defects can be found in the pyruvate dehydrogenase complex of enzymes and the electron transport chain complexes, which function in the oxidative decarboxylation of pyruvate to acetyl CoA, relating the disease to defects in the mitochondrial respiratory chain enzymes. Indeed, lactic acidosis is a feature of several of the mitochondrialopathies discussed later in this chapter. Cases examined postmortem have shown necrosis and cavitation of the globus pallidus and cerebral white matter. Possibly this is a variant of Leigh disease (page 843). It must be distinguished from the several diseases of infancy that are complicated secondarily by lactic acidosis, especially the organic acidopathies. Cases of benign transient infantile lactic acidosis have been reported, but their etiology is unclear.

Cerebrohepatorenal (Zellweger) Disease (Peroxisomal Disorder)

This disease, estimated to occur once in every 100,000 births, is inherited as an autosomal recessive trait. It has its onset in the neonatal period or early infancy and as a rule leads to death within a few months. Motor inactivity and hypotonia, dysmorphic alterations of the skull and face (high forehead, shallow orbits, hypertelorism, high arched palate, abnormal helices of ears, retrognathia), poor visual fixation, multifocal seizures, swallowing difficulties, fixed flexion posture of the limbs, cataracts, abnormal retinal pigmentation, optic atrophy, cloudy corneas, hepatomegaly, and hepatic dysfunction are the usual manifestations. Stippled, irregular calcifications of the patellae and greater trochanters are highly characteristic. Pathologically, there is dysgenesis of the cerebro cortex and degeneration of white matter as well as a number of visceral abnormalities—cortical renal cysts, hepatic fibrosis, intrahepatic biliary dysgenesis, agenesis of the thymus, and iron storage in the reticuloendothelial system.

As to the biochemical abnormality, A. B. Moser and coworkers have demonstrated a fivefold increase of very-long-chain fatty acids, particularly hexacosanoic acid, in the plasma and cultured skin fibroblasts from 35 patients with Zellweger disease. A similar abnormality was found in cultured amniocytes of women at risk of bearing a child with Zellweger disease, thus permitting prenatal diagnosis. The findings of Moser and colleagues are in keeping with current notions about the basic abnormality in Zellweger syndrome—namely, that it is due to a lack of liver peroxisomes (oxidase-containing, membrane-bound cytoplasmic organelles), in which the very-long-chain fatty acids are normally oxidized (Goldfischer et al).

Currently, a spectrum of at least 12 disorders of peroxisomal function is recognized, all of them characterized by deficiencies in the peroxisomal enzyme of fatty-acid oxidation—a veritable peroxisomal assembly. The most widely recognized are neonatal adrenoleukodystrophy and infantile Refsum disease, but the Zellweger cerebrohepatorenal syndrome can be considered the prototype. Each variant can be identified by its characteristic profile of elevated long- and very-long-chain fatty acids, and the specific diagnosis can be confirmed by enzymology of cultured fibroblasts or amniocytes. Several of them become manifest at a later age and are discussed further on. For an authoritative discussion of peroxisomal biogenesis, the reader is referred to the article by Gould and Valle.

The Oculocerebrorenal (Low) Syndrome

Here the mode of inheritance is probably X-linked recessive, although sporadic cases have been reported in girls. The abnormal gene is located on chromosome Xq25.26. The clinical abnormalities comprise bilateral cataracts (which may be present at birth), glaucoma, large eyes with megalocornea and buphthalmos, corneal opacities and blindness, pendular nystagmus, hypotonia and absent or depressed tendon reflexes, corticospinal signs without paralysis, slow movements of the hands, tantrums and aggressive behavior, high-pitched cry, occasional seizures, and psychomotor regression. Later the frontal bones become prominent and the eyes sunken. The characteristic biochemical abnormality is a renal tubular acidosis, and death is usually from renal failure. Additional laboratory findings include demineralization of bones and typical rachitic deformsities, anemia, metabolic acidosis, and generalized aminoaciduria. The neuropathologic changes are nonspecific; inconstant atrophy and poor myelination have been described in the brain and tubular abnormalities in the kidneys. The primary genetic defects are in the gene encoding inositol polyphosphate phosphatase of the Golgi complex. The main diagnostic distinction is from Zellweger disease. Treatment programs include anticonvulsant medication, correction of electrolyte disorders, and removal of cataracts.

Menkes Disease (Kinky- or Steely-Hair Disease; Trichopoliodystrophy)

This is a rare disorder, inherited as a sex-linked recessive trait. In most of the cases known to us, birth was premature. Poor feeding and failure to gain weight, instability of temperature (mainly hypothermia), and seizures become apparent in early infancy. The hair is normal at birth, but the secondary growth is lusterless and depigmented and feels like steel wool; hairs break easily and under the microscope they appear twisted (pili torti). Radiologic examination shows metaphyseal spurring, mainly of the femurs, and subperiosteal calcifications of the bone shafts. Arteriography discloses tortuosity and elongation of the cerebral and systemic arteries and occlusion of some. The combination of intracerebral hemorrhage and metaphyseal bone spurs, which may be interpreted as “corner fractures,” has led in some cases to the erroneous diagnosis of child abuse. There is no discernible neurologic development, and rarely does the untreated child survive beyond the second year. Treated with copper histidine, patients may survive to adolescence, but they remain profoundly impaired and hypotonic and require gastric feeding; the seizures may abate. Three of our cases have been examined postmortem (Williams et al). There was a diffuse loss of neurons in the relay nuclei of the thalamus, the cerebral cortex, and the cerebellum (granule and stellate cells) and of dendritic arborizations of residual neurons of the motor cortex and Purkinje cells.

The manifestations of this disease are attributable to a deficiency of several copper-dependent enzymes, including cytochrome oxidase, resulting in a failure of absorption of copper from the gastrointestinal tract and a profound deficiency of tissue copper (Danks et al). Further, since copper fails to cross the placenta, a severe reduction of copper in the brain and liver is evident from birth. In this sense, the abnormality of copper metabolism is the opposite of that in Wilson disease. A relationship between Wilson and Menke disease is nonetheless evident at a genetic level since they arise from genes encoding two different copper-transporting proteins that are both ATPases. Parenteral administration of cupric
salts restores the serum and hepatic copper but does not materially influence the neurologic symptoms, as noted above.

**Diagnosis of Inherited Metabolic Diseases of Infancy**

It will be recognized from the foregoing synopses that many of the neurologic manifestations of the inherited metabolic diseases of infancy are nonspecific and are common to most or all of the diseases in this group. In general, in the early stages of all these diseases, there is a loss of postural tone and a paucity of movement without paralysis or loss of reflexes; later there is spasticity with hyperreflexia and Babinski signs. Equally nonspecific are features such as irritability and prolonged crying; poor feeding, difficulty in swallowing, inanition, and retarded growth; failure of fixation of gaze and following movements of the eyes (often misinterpreted as blindness); and tonic spasms, clonic jerks, and focal and generalized seizures.

The differentiation of the inherited metabolic diseases of infancy rests essentially upon four types of data: (1) a few highly characteristic neurologic and ophthalmic signs; (2) the presence of an enlarged liver and/or spleen; (3) special dysmorphic features of the face; and (4) the results of several relatively simple laboratory tests, such as radiographs of the thoracolumbar spine, hips, and long bones; smears of the peripheral blood and bone marrow; CSF examination; and certain urinary tests and other biochemical estimations (serum lactate, glucose, ammonia, and urinary ketones, amino acids, and organic acids). For purposes of differential diagnosis, we have found the flowcharts constructed by our colleague E. Kolodny to be most serviceable. One such schematic, illustrated in Fig. 37-4, is based on the subdivision of patients into three groups: (1) dysmorphic, (2) visceromegalic, and (3) purely neurologic. Only rarely does an inherited metabolic disease fall into more than one of these categories. There is also considerable value in beginning the diagnostic process by classifying the syndrome as a leukodystrophy or a poliodystrophy (disease predominantly affecting neurons, see further on), although this distinction is easier to make in the older child.

  - Globoid-body (Krabbe)
  - Metachromatic leukodystrophy

*Figure 37-4.* A schematic for diagnosis of the inherited metabolic diseases of infancy. (Courtesy of Dr. Edwin Kolodny.)
Once the patient is placed in one of these major categories, correct diagnosis then depends on the recognition of particular clinical and laboratory features, tabulated below (see also Tables 37-5 and 37-6).

Neurologic signs that are more or less specific for certain metabolic diseases are as follows:

1. Acoustocmotor obligatory startle: Tay-Sachs disease
2. Abolished tendon reflexes with definite Babinski signs: globoid cell (Krabbe) leukodystrophy, occasionally Leigh disease, and (beyond infancy) metachromatic leukodystrophy
3. Peculiar eye movements, pendular nystagmus, and head rolling: Pelizaeus-Merzbacher disease, Leigh disease; later, hyperbilirubinemia and Lesch-Nyhan hyperuricemia (see below)
4. Marked rigidity, opisthotonus, and tonic spasms: Krabbe, Alpers disease, or infantile Gaucher disease (classic triad: trismus, strabismus, opisthotonos)
5. Intractable seizures and generalized or multifocal myoclonus: Alpers disease
6. Intermittent hyperventilation: Leigh disease and congenital lactic acidosis (also nonprogressive familial agenesis of vermis)
7. Strabismus, hypotonia, seizures, lipodystrophy: carbohydrate-deficient glycoprotein syndrome

Ocular abnormalities of specific diagnostic value in this age group are as follows:

1. Rapid pendular nystagmus: Pelizaeus-Merzbacher disease, rarely Krabbe leukodystrophy, Cockayne syndrome (later age)

**Diagnostic biochemical abnormality:** see text.

**SOURCE:** Adapted from Drew AL Jr, with permission.

---

2. Macular cherry-red spots: Tay-Sachs disease and Sandhoff variant, some cases of infantile Niemann-Pick disease, and rarely lipofuscinosis (see Table 37-4)

3. Corneal opacification: Lowe disease, infantile GM1 gangliosidosis; later, the mucopolysaccharidoses

4. Cataracts: galactosemia, Lowe disease, Zellweger disease (also congenital rubella)

Several other medical findings are of specific diagnostic value:

---

1. Dysmorphic facies; generalized GM1 gangliosidosis, Lowe and Zellweger syndromes, and some early cases of mucopolysaccharidosis and mucolipidosis

2. Enlarged liver and spleen: infantile Gaucher disease and Niemann-Pick disease; one type of hyperammonemia; Sandhoff disease; later, the mucopolysaccharidoses and mucolipidoses

3. Enlarging head without hydrocephalus (macrocephaly): Canavan spongy degeneration of infancy, some cases of Tay-Sachs disease, Alexander disease

4. Beaking of vertebral bodies in radiographs: GM1 gangliosidosis (and, at a more advanced age, the mucopolysaccharidoses, fucosidosis, mannosidosis, and the mucolipidoses)

5. Multiple arthropathies and raucous dysphonia: Farber disease

6. Storage granules and vacuolated lymphocytes: Niemann-Pick disease, generalized GM1 gangliosidosis
7. Abnormal histiocytes in marrow smears: Gaucher cells, foamy histiocytes in Niemann-Pick disease, generalized GM1 gangliosidosis and closely related diseases, Farber disease
8. Colorless, friable hair: Menkes disease

**INHERITED METABOLIC DISEASES OF EARLY CHILDHOOD**

Included here are the diseases that become manifest between the ages of 1 and about 4 years. Diagnosis is less difficult than in the neonate and young infant. A pathologic process in the nervous system is reliably ascertained by the obvious progression of a neurologic disorder, such as a loss of ability to walk and to speak, which usually parallels a regression in other high-level (quasi-intellectual) functions. Embryologic anomalies, prenatal diseases, and birth injuries can be excluded with relative certainty if psychomotor development was normal in the first year or two. Diseases characterized by seizures and myoclonus may prove more difficult to interpret, for the seizures may occur at any age from a variety of distant or immediate neurologic causes and, if frequent, may cause a significant impairment of psychomotor function. The effects of anticonvulsant medications may add to the impairment of cortical function. Unfortunately, most of the slowly advancing metabolic diseases of the second year may be so subtle in their effects that for a time the physician cannot be sure whether a regression of intellectual functions is taking place or mental retardation or autism is becoming apparent for the first time. An added difficulty arises when, for a number of years, the hereditary metabolic abnormality merely slows development. To distinguish metabolic disease from developmental retardation is more difficult if the parents have been unobservant. Repeated examinations and testing will usually settle the matter. Suspicions of a progressive encephalopathy is heightened by the presence of certain ocular, visceral, and skeletal abnormalities, as described below.

Once a neurologic syndrome is clearly established, there is a particular advantage in determining whether its main characteristics reflect a disorder of the cerebral white matter (oligodendrocytes and myelin) or of gray matter (neurons). Indicative of predominantly white matter affection (leukodystrophy or leukoencephalopathy) are early onset of spastic paralysis of the limbs, with or without ataxia, and visual impairment with optic atrophy but normal retinas. Seizures and intellectual deterioration are late events. MRI usually confirms the involvement of white matter. Indicative of gray matter disease (poliodystrophy or polioencephalopathy) are the early onset of seizures, myoclonus, blindness with retinal changes, and mental regression. Choreothetosis and ataxia, spastic paralysis, and signs of sensorimotor tract involvement occur later. On MRI, only a generalized atrophy and ventricular enlargement may be seen.

Neuronal storage diseases, such as those described in the previous section, as well as neuroaxonal dystrophy and the lipofuscinoses, conform to the pattern of gray matter diseases (Table 37-5). Metachromatic globoid-body (Krabbe) disease, sudanophilic leukodystrophy, and spongy degeneration of infancy (Canavan disease) exemplify white matter diseases (Table 37-6). Although this mode of categorization is helpful, there is some degree of overlap; for example, Tay-Sachs disease, a poliodystrophy, also causes white matter changes, and metachromatic leukodystrophy may be accompanied by some degree of neuronal storage.

The following are inherited metabolic diseases that become evident clinically in late infancy and early childhood:

1. Many of the milder disorders of amino acid metabolism
2. Metachromatic and other leukodystrophies
3. Late infantile GM1 gangliosidosis
4. Late infantile Gaucher disease and Niemann-Pick disease
5. Neuroaxonal dystrophy
6. The mucopolysaccharidoses
7. The mucolipidoses
8. Fucosidosis
9. The mannosidoses
10. Aspartylglucosaminuria
11. Ceroid lipofuscinosis (Jansky-Bielschowsky disease)
12. Cockayne syndrome

**The Aminoacidopathies** (Aminoacidurias)

In a group of 48 inherited aminoacidopathies tabulated by Rosenberg and Scriver, at least one-half were associated with recognizable neurologic abnormalities. Twenty other aminoacidopathies result in a defect in the renal transport of amino acids, some of which secondarily damage the nervous system. Usually, when the nervous system is involved, the only clinical manifestation is simply a lag in psychomotor development, which, if mild, does not become apparent until the second and third years or later. Like other inherited metabolic disorders, the aminoacidurias do not impair growth, development, or maturation in utero or interfere with parturition. (This is the result of the maternal blood supply, which defines the amino acid balance in utero.) No physical sign betrays their presence in the early months of life. The only possible means of detection is by the screening of all newborns. The relative frequency of these diseases is indicated in Table 37-1, and the practical tests for their identification are summarized in Table 37-2.

Three aminoacidopathies of the late infantile and early childhood period—phenylketonuria (PKU), tyrosinemia, and Hartnup disease—are described here because of their clinical importance and because they exemplify different types of biochemical defect. Reference is also made to certain other aminoacidurias, described in the first part of this chapter, which, like Hartnup disease, are associated with intermittent ataxia. Only passing comments are made about the other aminoacidurias, which are exceedingly rare or have only an uncertain effect on the nervous system. A detailed and relatively current account of these disorders can be found in the monograph of Scriver and coworkers.

**The Phenylketonurias (PKU, Phenylalanine Hydroxylase Deficiency)** Apart from being the most frequent of the aminoacidurias, this entity has a special historical significance. Since its discovery by Folling in 1934, it has remained the classic example of an aminoaciduria and illustrates three principles of medical genetics: first, it is inherited as an autosomal recessive trait; second, it exemplifies Garrod’s cardinal principle of gene action, in which genetic factors specify chemical reactions as well as biochemical individuality; third, PKU is expressed only in an environment that contains an abundance of l-phenylalanine. Thus, as predicted by Galton, the ultimate phenotype is a product of “nature and nurture” (Scriver and Clow).

One must refer to the phenylketonurias in the plural, for there are (1) the usual type and several mild and severe variants thereof,
in all of which mental retardation is invariable if the disease is not treated early in life, (2) other types, presumably allelic mutations, in which there is hyperphenylalaninemia without PKU and without effect on the nervous system, and (3) a rare adult type with a progressive spastic paraparesis or without neurologic manifestations. Also there are a small number of patients (3 percent in our series) in whom a lowering of the hyperphenylalaninemia does not prevent the progression of the neurologic lesion.

At birth, the typical PKU infant is believed to have a normal nervous system. The disease appears later, only after long exposure of the nervous system to phenylalanine (PA), because the homozygous infant lacks the means of protecting the nervous system. However, if the mother is homozygous with high PA levels in the blood during pregnancy, the CNS is damaged in utero and the heterozygous infant is mentally defective from birth.

In the classic form of PKU, the impairment of psychomotor development can usually be recognized in the latter part of the first year, when expected performance lags. By 5 to 6 years in an untreated child, when the IQ can be estimated, it is usually less than 20, occasionally 20 to 50, and exceptionally above 50. Hyperactivity, aggressivity, self-injury behavior—including severe injury to the eyes, clumsy gait, fine tremor of the hands, poor coordination, odd posturings, repetitive digital mannerisms and other so-called rhythmias, and slight corticospinal tract signs stand out as the main clinical manifestations. Athetosis, dystonia, and frank cerebellar ataxia have been described but must be exceedingly rare. Also, seizures are said to occur in 25 percent of severely retarded patients, taking the form at first of flexor spasms and later of absence and grand mal attacks. However, of more than 30 PKU patients at the Fernald School, a number of which we have followed clinically, none had seizures or extrapyramidal signs. The majority are blue-eyed and fair in skin and hair color, and their skin is rough and dry and subject to eczema. A musty body odor (due to phenylacetic acid excretion) can often be detected. Two-thirds are slightly microcephalic. The fundi are normal, and there is no visceral enlargement or skeletal abnormality.

There are individuals living in the community with asymptomatic PKU and normal intelligence. Instances of PKU in which the symptoms are of adult onset are rare but of interest because of the entirely unexpected diagnosis. The few such cases reported and summarized by Kassim and colleagues, with a case of their own, have developed a progressive spastic paraparesis, some with mild dementia. The phenylalanine levels have been at values that reflect total or partial enzyme deficiency.

The finding of high levels of serum phenylalanine (above 15 mg/dL) and of phenylpyruvic acid in the blood, CSF, and urine are diagnostic of PKU. The level is normal at birth and rises only after the first few days. But screening by the Guthrie (ferric chloride) test will reliably identify the patient at risk. The addition of 3 to 5 drops of 10% ferric chloride to 1 mL of urine is a simple and informative test. It yields an emerald-green color that reaches a peak intensity in 3 to 4 min and fades in 20 to 40 min. In contrast, the green-brown color in the urine of patients with histidinemia is permanent. In maple syrup urine disease, the ferric chloride test gives a navy-blue color; propionic and methylmalonic acidemia and either ketones or salicylates in the urine yield a purple color.

The fundamental biochemical abnormality is a deficiency of the hepatic enzyme PA hydroxylase; the failure of conversion of PA to tyrosine results in the excretion of phenylpyruvic acid by affected individuals. The precise step that is faulty in the complex phenylalanine hydroxylating reaction is still unknown.

Pathologic examination shows poor staining of myelin in the cerebral hemispheres. This can be visualized by MRI in untreated children. Another curious feature is that the usually pigmented nuclei (substantia nigra, locus ceruleus, dorsal vagal motor) fail to acquire dark coloration because of a block in the production of melanin. Reduction in size of cortical neurons and their dendritic arborizations is said to be demonstrable in some cases.

**Treatment** If instituted in infancy, diets low but not totally lacking in PA can improve intellectual development (blood level should be maintained at 5 to 10 mg/dL). Once the neurologic picture unfolds, diet has little or no effect on the mental status but may improve behavior. Prolonged dietary treatment has many untoward effects and should be supervised by physicians and nutritionists experienced in its use; if too restricted, it may retard growth. This is particularly important, since it has been shown that intellectual impairment is greatest among children who were the earliest to abandon their diets, permitting the PA concentration to rise above 15 mg/dL, and least in children who maintained dietary control the longest (Holtzman et al). Continued dietary treatment is necessary. With the widespread screening for PKU and the initiation of dietary control during early postnatal life, this metabolic brain disease has virtually disappeared in the New England states. Treated women who reach childbearing age should be particularly careful about dietary restriction, since high levels of phenylalanine are harmful to the normal fetus. Mild cases of PKU have been successfully treated with the cofactor tetrahydrobiopterin (Muntau et al).

The late forms of maple syrup urine disease, histidinemia, and hydroxyprolinemia evolve in much the same fashion as PKU and raise similar problems in diagnosis and therapy.

A small number of infants have a variant of PKU in which a restricted PA diet does not prevent neurologic involvement. In some such infants, a dystonic extrapyramidal rigidity (“stiff-baby syndrome”) has appeared as early as the neonatal period, and, according to Allen and coworkers, it responds to biopterin. Such infants have normal levels of PA hydroxylase in the liver. The defect is a failure to synthesize the active cofactor tetrahydrobiopterin, because of either an insufficient dihydropteridine reductase or an inability to synthesize biopterin (see page 801). The urinary metabolites of catecholamines and serotonin are reduced and are not responsive to low-PA diets. There is some evidence that the underlying neurotransmitter fault can be corrected by L-dopa and by 5-hydroxytryptophan (Scriven and Clow).

**Hereditary Tyrosinemia (Oculocutaneous Tyrosinemia; Richner-Hanhart Disease)** This is a rare, predominantly dermatologic aminoacidopathy, but in approximately one-half of the infants there is a mild to moderate degree of mental retardation. Also, as in some other aminoacidopathies, there may be self-mutilation and incoordination of limb movements. Language defects are prominent. Toward the end of the first or second year of life, lacrimation, photophobia, and redness of the eyes (due to corneal erosions) appear. Neovascularization of the corneas and opacification follow. Palmar and plantar keratosis with hyperhydrosis and pain are frequently present as a result of an inflammatory reaction to deposits of crystalline tyrosine (also the cause of the corneal changes). Elevated tyrosine in the blood (>0.18 mM) and urine are diagnostic. The disease is due to a gene defect on chromosome 15 that codes for the enzyme fumarylactoacetate hydrolase, a deficiency of which results in the accumulation of tyrosine and its metabolites.

A low-tyrosine and low-PA diet, optimized to allow growth
and development, has resulted in rapid amelioration of symptoms but must be started early. Retinoids given orally improve the skin lesions. Neonatal tyrosinemia can cause liver failure and early death. This disease can be distinguished from the Cross syndrome (albinism with mental retardation, growth impairment, spastic weakness, and alkalosis) and from the Waardenburg ocular albinism syndrome (white forelock, hypertelorism, deafness). For a detailed discussion of the albinism syndromes, see the article by Oetting and King.

Tyrosine Hydroxylase Deficiency  This relatively recently described disease causes a progressive infantile encephalopathy; it is of special interest because tyrosine is the precursor of L-dopa and the other catecholamines. Levels of these chemical substances in the brain are greatly reduced. As a result, the encephalopathy takes the form mainly of fluctuating extrapyramidal signs in combination with ocular and vegetative symptoms. L-Dopa causes some improvement in the motor symptoms (see Hoffmann et al). This disease has implications for juvenile dopa-responsive dystonia, which is exquisitely sensitive to L-dopa treatment (as discussed on page 930) and is contrasted with the deficiency of L-amino decarboxylase, described above, which also causes low levels of catecholamines and a movement disorder.

Hartnup Disease  This amino acid disorder, named after the family in which it was first observed, is probably transmitted in an autosomal recessive pattern. Women carrying this trait deliver babies who are normal at birth. The onset of symptoms is in late infancy or early childhood. The clinical features consist of an intermittent red, scaly rash over the face, neck, hands, and legs, resembling that ofpellagra. It is often combined with an episodic personality disorder in the form of emotional lability, uncontrollable temper, and confusional-hallucinatory psychosis; episodic cerebellar ataxia (unsteady gait, intention tremor, and dysarthria); and occasionally spasticity, vertigo, nystagmus, ptosis, and diplopia. Attacks of disease are triggered by exposure to sunlight, emotional stress, and sulfonamide drugs and last for about 2 weeks, followed by variable periods of relative normalcy. The frequency of attacks diminishes with maturation, but some children suffer retarded growth and development with a mild persistent mental retardation.

The metabolic faults are due to a transport error of neutral amino acids across renal tubules, with excretion of greatly increased amounts of these amino acids in the urine and feces. In particular, there is the excretion of large amounts of indicans, mainly indoxyl sulfate, particularly after oral L-tryptophan loading, and an abnormally high excretion of nonhydroxylated indole metabolites. Impaired intestinal transport of tryptophan and loss in the urine reduces its availability for the synthesis of niacin and accounts for the pellagrous skin changes. The pathologic basis of the disease is undetermined. It must be differentiated from the large number of intermittent and progressive cerebellar ataxias of childhood, described below.

Treatment consists of avoiding exposure to sunlight and to sulfonamide drugs. Because of the similarities between pellagra and Hartnup disease, the usual practice is to give nicotinamide in doses of 50 to 300 mg daily. The skin lesions disappear and there are reports of subsidence of ataxia and psychotic behavior. However, the results of treatment are inconsistent. Possibly a better response is obtained by the administration of L-tryptophan ethyl ester in doses of 20 mg/kg thrice daily.

Other Metabolic Diseases with Episodic or Persistent Ataxia, Seizures, and Mental Retardation  In addition to Hartnup disease, a number of other metabolic diseases give rise to intermittent episodes of ataxia during early childhood. These are (1) mild forms of maple syrup urine disease and the congenital hyperammonemias (type II hyperammonemia, citrullinemia, arginosuccinic aciduria, hyperornithinemia), described in an earlier part of the chapter; (2) necrotizing encephalomyelopathy (Leigh disease), described further on; (3) hyperalaninemia and hyperpyruvic acidemia (Lonsdale et al, Blatt et al); and (4) autosomal dominant, acetazolamide-responsive ataxia that may have its onset in childhood but usually appears later (page 827).

In all these conditions the ataxia, which is of cerebellar type, is highly variable from time to time and may follow a burst of seizures (such as occur in arginosuccinic aciduria). The seizures are treated with anticonvulsant drugs, which may at first be held responsible for the ataxia. In time, however, it becomes apparent that the ataxia lasts a week or two and bears no relation to the anticonvulsant therapy. Indeed, seizures and ataxia are both due to the common biochemical abnormality. Between attacks, in all the intermittent ataxias, the patient’s movements are relatively normal, but most of the affected children are slow in learning and remain backward mentally to a varying degree.

The Problem of Progressive Cerebellar Ataxia of Early Childhood  The differentiation of the childhood ataxias is difficult. The problem is twofold—first, to be certain that ataxia exists, and, second, to differentiate cerebellar ataxia from the sensory ataxia of peripheral nerve disease and from generalized tremor and polykineses. Since cerebellar ataxia is more a disorder of voluntary than of postural movements, its presence usually cannot be determined with certainty until intentional (projected) movements become part of the child’s repertoire of motor activity. As indicated in Chap. 28, the earliest signs become manifest in the arms when the infant reaches for an object and brings it to his mouth or transfers it from hand to hand. A jerky, wavering, tremulous movement then appears; in sitting, a titubation of the head and a tremor of the trunk may be apparent. Once walking begins, apart from the usual clumsiness of the toddler, there is a similar incoordination of movement. Sensory ataxia is always difficult to distinguish but is rare at this age and usually accompanied by weakness and absence of tendon reflexes. By the fourth or fifth year, when more detailed sensory testing becomes possible, the presence or absence of a proprioceptive disturbance and a Romberg sign can be demonstrated.

The group of persistent and progressive cerebellar ataxias is heterogeneous and of varied etiology; some of them merge with Friedreich ataxia, Levy-Roussy neuropathy, and other adolescent/adult degenerative hereditary ataxias. These disorders are discussed in Chap. 39 on degenerative diseases, since, apart from their hereditary nature, neither their cause nor their pathogenesis is known. There are many other childhood ataxias that probably belong in the category of degenerative disease, some in which cerebellar ataxia is the most prominent disorder and in which other neurologic abnormalities are more prominent. To describe each in detail would be impractical in a book on the principles of neurology; therefore, the non-Friedreich ataxias are only tabulated here.

1. The disequilibrium and dyssynergia syndrome of Hagberg
and Janner: early-life onset of relatively pure cerebellar ataxia, with psychomotor retardation.

2. Cerebellar ataxia with diplegia, hypotonia, and mental retardation (also called atonic diplegia of Foerster); this is either a fetal disease or birth (cerebral palsy).

3. Agenesis of the cerebellum: early cerebellar ataxia (with or without mental retardation) and episodic hyperventilation (Norman’s family with granule-cell degeneration falls into this category).

4. Cerebellar ataxia with cataracts and oligophrenia: onset from childhood (mainly) to as late as adult years (Marinesco-Sjögren disease).

5. Familial cerebellar ataxia and retinal degeneration (Behr).

6. Familial cerebellar ataxia with cataracts and ophthalmpoplegia or with cataracts and mental as well as physical retardation.

7. Familial cerebellar ataxia with mydriasis.

8. Familial cerebellar ataxia with deafness and blindness and a similar combination, called retinocochleodegeneration, involving the loss of neurons in these three structures.

9. Familial cerebellar ataxia with choreoathetosis, corticospinal tract signs, and mental and motor retardation.

In none of the syndromes mentioned above has a biochemical abnormality been established, so their metabolic nature is a matter of speculation. However, disorders of the electron transport chain can, on occasion, present as the Marinesco-Sjögren phenotype, mentioned above.

The persistent cerebellar ataxias of childhood in which a metabolic fault or gene defect has been demonstrated are as follows:

1. Refsum disease

2. Abetalipoproteinemia (Bassen-Kornzweig syndrome)

3. Ataxia-telangiectasia

4. Galactosemia

5. Possibly Friedreich ataxia

Refsum disease is discussed with the hereditary polyneuropathies (page 1157).

The Bassen-Kornzweig syndrome has its onset more often in late than in early childhood and is more appropriately described in the following section of this chapter. Ataxia-telangiectasia is described below. Galactosemia has been described on page 802 and Friedreich ataxia on page 949. Generally, it is not difficult to differentiate these diseases from the acquired postinfectious variety that occurs predominantly in children.

**Ataxia-Telangiectasia** This disease, sometimes referred to as the *Louis-Bar syndrome*, was first described by Sylaba and Henner in 1926, long before Louis-Bar’s report in 1941. It combines a progressive ataxia with humoral immune deficiency and telangiectasias. Like xeroderma pigmentosum and the Cockayne syndrome, ataxia-telangiectasia has been attributed to defective repair of DNA. The inheritance pattern is autosomal recessive.

The disorder first presents as an ataxic-dyskinetic syndrome in children who appear to have been normal in the first few years of life. The onset of the disease coincides more or less with the acquisition of walking, which is awkward and unsteady. Later, by the age of 4 to 5 years, the limbs become ataxic, and choreoathetosis, grimacing, and dysarthric speech are added. The eye movements become jerky, with slow and long-latency saccades, and there is also apraxia for voluntary gaze (the patient turns the head but not the eyes on attempting to look to the side). Optokinetic nystagmus is lost. By the age of 9 to 10 years, slight intellectual decline sets in and signs of mild polyneuropathy are evident. Muscle power is reduced little if at all until late in the illness, but tendon reflexes may disappear. The characteristic telangiectatic lesions, which are mainly transversely oriented subpapillary venous plexuses, appear at 3 to 5 years of age or later and are most apparent in the outer parts of the bulbar conjunctivae (Fig. 37-5), over the ears, on exposed parts of the neck, on the bridge of the nose and cheeks in a butterfly pattern, and in the flexor creases of the forearms. Vitiligo, café-au-lait spots, loss of subcutaneous fat, and premature graying of hair are observed in some patients. Many of the patients have endocrine alterations (absence of secondary sexual development, glucose intolerance). The disease is progressive, and death usually occurs in the second decade from intercurrent bronchopulmonary infection or neoplasia—usually lymphoma, less often glioma (Boder and Sedgwick).

The significant abnormalities in the CNS are severe degeneration in the cerebellar cortex (visible in MRI scans); loss of myelinated fibers in the posterior columns, spinocerebellar tracts, and peripheral nerves; degenerative changes in the posterior roots and cells of the sympathetic ganglia; and loss of anterior horn cells at all levels of the spinal cord. In a few cases, vascular abnormalities, like the mucocutaneous ones, have been found scattered diffusely in the white matter of the brain and spinal cord, but they are of questionable significance. Also, there may be a loss of pigmented cells in the substantia nigra and locus ceruleus (a feature shared with PKU), and cytoplasmic inclusions (Lewy bodies) in the cells that remain (Agamanolis and Greenstein). During early development there are abnormalities of Purkinje cell migration and variations in nuclear size. Intranuclear inclusions and bizarre nuclear formations have also been found in the satellite cells (amphicytes) of dorsal root ganglion neurons (Strich).

There is an absence or decrease in several immunoglobulins—IgA, IgE and isotypes, IgG2, IgG4—in practically every patient.

*Figure 37-5. Ocular appearance of ataxia-telangiectasia. (Reproduced by permission from Lyon et al.)*
These deficiencies, shown by McFarlin and associates to be due to decreased synthesis, are associated with hypoplasia of the thymus, loss of follicles in lymph nodes, failure of delayed hypersensitivity reactions, lymphopenia, and slow formation of circulating antibodies. Probably this immunodeficient state accounts for the striking susceptibility of these patients to recurrent pulmonary infections and bronchiectasis. Transplantation of normal thymus tissue into the patient and administration of thymus extracts have been of no therapeutic value.

The defective gene (designated ATM) is a kinase that mediates DNA repair by halting the cell cycle after DNA damage. For this reason, there is faulty repair of DNA after radiation and a greatly increased risk of lymphomas, leukemias, and other tumors.

The only therapy centers on the control of infections. Free radical scavengers such as vitamin E have been recommended without proof of their effectiveness. Because of radiation sensitivity, even conventional diagnostic tests (dental, chest x-ray) should be avoided unless there is a compelling reason for them.

Metachromatic Leukodystrophy (MLD, Arylsulfatase Deficiency)

This is another of the lysosomal ( sphingolipid ) storage diseases (Table 37-3). The basic abnormality, localized in chromosome 22, is the absence of the gene for enzyme arylsulfatase A, a deficiency of which prevents the conversion of sulfatide to cerebroside (a major component of myelin) and results in an accumulation of the former. The disease is transmitted as an autosomal recessive trait and usually becomes manifest between the first and fourth years of life (variants have their onset in the congenital period, in late childhood, and even in adult life). Variability of gene mutation accounts for the different forms. The so-called “O” type mutation causes a lack of active gene product and of the corresponding enzyme; the “R” type mutation results in low levels. The infantile form is associated with two copies of the O gene, the juvenile form, with either O or R, and the adult form is usually from two copies of R. Another genetic classification system denominates “I” and “A” alleles and differentiates the types of disease by age of onset and residual enzyme activity.

The disease in this age group is characterized clinically by progressive impairment of motor function (gait disorder, spasticity) in combination with reduced output of speech and mental regression. At first the tendon reflexes are usually brisk, but later, as the peripheral nerves become more involved, the tendon reflexes are decreased and eventually lost. Or, there may be variable hypotonia and areflexia from the beginning, or spasticity may be present throughout the illness, but with hyporeflexia and slowed conduction velocities. Signs of mental regression may be apparent from the onset or appear after the motor disorder has become established. Later there is impairment of vision, sometimes with squint and nystagmus; intention tremor in the arms and dysarthria; dysphagia and drooling; and optic atrophy (one-third of patients), sometimes with nystagmus; intention tremor in the arms and dysarthria; dysphagia and drooling; and optic atrophy (one-third of patients), sometimes with grayish degeneration around the maculae. Seizures are rare, and there are no somatic abnormalities. The head size is usually normal, but rarely there is macrocephaly. Progression to a bedridden quadriplegic state without speech or comprehension occurs over a 1- to 3-year period, somewhat more slowly in late-onset types. The CSF protein is elevated.

There is widespread degeneration of myelinated fibers in the cerebrum (Fig. 37-6), cerebellum, spinal cord, and peripheral nerves. The presence of metachromatic granules in glial cells and engorged macrophages is characteristic and enables the diagnosis to be made from a biopsy of a peripheral nerve. The stored material, sulfatide, stains brown-orange rather than purple with aniline dyes. Sulfatides are also PAS-positive in frozen sections.

The differential diagnosis of this leukodystrophy is from neuroaxonal dystrophy (see below), cases of early-onset inherited polynyropathy, late-onset Krabbe disease, and childhood forms of Gaucher disease and Niemann-Pick disease. A variant of metachromatic leukoencephalopathy, due to a deficiency of the isoenzymes of arylsulfatase A, B, and C, was described by Austin in 1973. He called it multiple sulfatase deficiency. The neurologic manifestations resemble those of metachromatic leukodystrophy, but, in addition, there are facial and skeletal changes similar to those of a mucopolysaccharidosis. Deafness, hepatic enlargement, ichthyosis, and beaking of lumbar vertebrae are additional findings.

Figure 37-6. Metachromatic leukodystrophy. T2-weighted axial MRI of a 3-year-old boy. Abnormal high signal intensity involves the entire centrum ovale but spares the subcortical arcuate fibers. (Reproduced by permission from Lee SH, Rao K, Zimmerman RA: Cranial MRI and CT, 3rd ed. New York, McGraw-Hill, 1992.)
in some cases. Metachromatic material is found in the urinary sediment. Pathologically, in addition to metachromasia of degenerating white matter in cerebrum and peripheral nerve, there may be storage material (sulfated glycolipids), like that found in the gangliosidoses in neurons as well as in liver, gallbladder, and kidney. Granules are demonstrable in neutrophilic leukocytes. There has also been described a state of “arylsulfatase pseudodeficiency,” which exists as a polymorphism in about 7 percent of Europeans and makes the point that low enzyme levels alone are insufficient to be expressed as a phenotype of metachromatic leukodystrophy.

Forms of metachromatic leukodystrophy developing in adult years are discussed further on.

**Neuroaxonal Dystrophy (Degeneration)**

This is a rare disease, inherited as an autosomal recessive trait. In the largest group of cases (77 collected by Aicardi and Castelein), the onset was near the beginning of the second year in 50 patients and before the third year in all instances. The clinical constellation comprised psychomotor deterioration (loss of ability to sit, stand, and speak), marked hypotonia but brisk reflexes and Babinski signs, and progressive blindness with optic atrophy but normal retinæ. Seizures, myoclonus, and extrapyramidal signs were rare. Loss of sensation was found later in some cases. Terminally, bulbar signs, spasticity, and decerebrate rigidity often supervened. The course was relentlessly progressive, with fatal issue in a decorticat state in 3 to 8 years. There were no abnormalities of the liver and spleen and no facial or skeletal changes.

Pathologic examination reveals eosinophilic spheroids of swollen axoplasm in the posterior columns and nuclei of Goll and Burdach and in Clarke’s column, substantia nigra, subthalamic nuclei, central nuclei of brainstem, and cerebral cortex. There is cerebellar atrophy, affecting the granule cell layer predominantly, and increased iron-containing pigment in the basal ganglia (like that observed in Hallervorden-Spatz disease).

The CT scans and CSF are normal, and there are no biochemical or blood cell abnormalities. After the age of 2 years, however, the EEG shows characteristic high-amplitude fast rhythms (16 to 22 Hz). Evoked responses may be abnormal. Nerve conduction velocities are normal despite EMG evidence of denervation. The diagnosis can be reliably established during life by electron microscopic examination of skin and conjunctival nerves, which show the characteristic spheroids within axons.

There is a later-onset form of the disease in which the course is more protracted and the neurologic manifestations (rigidity and spasticity, cerebellar ataxia, and myoclonus) are more pronounced. In these cases the mental regression is slow. Vision may be retained, but retinal degeneration has been documented. Some of the late-onset cases are indistinguishable from Hallervorden-Spatz disease (page 832).

The primary mutation in most cases is unknown. In early infantile forms there is a mutation in a lysosomal hydrolase.

**Late Infantile and Early Childhood Gaucher Disease**

As stated earlier, Gaucher disease usually develops in early infancy, but some cases, so-called Gaucher disease type III, may begin in childhood, between 3 and 8 years of age. The clinical picture is variable and combines features of infantile Gaucher disease—such as abducens palsies, dysphagia, trismus, rigidity of the limbs, and dementia—with features of the late childhood–early adult form, such as palsies of horizontal gaze, diffuse myoclonus, generalized seizures, and a chronic course (Winkelman et al). The diagnosis is established by the finding of splenomegaly, Gaucher cells, glucocerebroside storage, and deficient activity of glucocerebrosidase in leukocytes or cultured fibroblasts.

**Late Infantile–Early Childhood Niemann-Pick Disease**

A number of cases of subacute or chronic neurovisceral storage diseases with early signs of hepatosplenomegaly and later signs (2 to 4 years) of neurologic involvement have been described. Crocker and Farber classified them as types III and IV Niemann-Pick disease. Others have classified them as types C and D, although it is now generally agreed that they are best considered a single entity.

The neurologic disorder consists of progressive dementia, ataxia, rarely extrapyramidal signs (choreoathetosis), and paralysis of horizontal and vertical gaze, the latter being a distinguishing feature. On attempting to look to the side, some of the patients make head-thrusting movements of the same type that one observes in ataxia-telangiectasia and the oculomotor apraxia of Cor gán (page 873). Lateral eye movements are full on passive movement of the head (oculocephalic maneuver). Convergence is also deficient. A special syndrome called juvenile dystonic lipidosis is characterized by extrapyramidal symptoms and paralysis of vertical eye movements. The syndrome of the “sea-blue histiocyte” (liver, spleen, and bone marrow contain histiocytes with sea-blue granules)—in which there is retardation in mental and motor development, grayish macular degeneration, and, in one of our cases, posterior column and pyramidal degeneration—may be another variant.

The diagnosis is made by bone marrow biopsy, which discloses vacuolated macrophages and sea-blue histiocytes, and by measuring the defect in cholesterol esterification in cultured fibroblasts.

**Late Infantile–Childhood GM₁ Gangliosidosis**

In type 2 or so-called juvenile GM₁ gangliosidosis, the onset is between 12 and 24 months, with survival for 3 to 10 years. The first sign is usually difficulty in walking, with frequent falls, followed by awkwardness of arm movements, loss of speech, severe mental regression, gradual development of spastic quadriaparesis and pseudobulbar palsy (dysarthria, dysphagia, drooling), and seizures. Retinal changes are variable—usually they are absent, but macular red spots may be seen at the age of 10 to 12 years; vision is usually retained, but squints (comitant) are common. There is a facial dysmorphism resembling that of the Hurler syndrome, and the liver and spleen are enlarged. Important laboratory findings are hypoplasia of the thoracic column vertebral bodies, mild hypoplasia of the acetabula, and the presence in the bone marrow of histiocytes with clear vacuoles or wrinkled cytoplasm. As noted on page 807, leukocytes and cultured skin fibroblasts show a deficiency or absence of β-galactosidase activity. GM₁ ganglioside accumulates in the cerebral neurons.

**The Neuronal Ceroid Lipofuscinoses (Batten Disease)**

As a group, the lipofuscinoses have been the most frequent of the neurodegenerative diseases of infancy and childhood diagnosed at
the Lysosomal Enzyme Laboratory of the E. K. Shriver Center. Four types have been identified: Santavuori-Haltia Finnish infantile type, Jansky-Bielschowsky early-childhood type, Vogt-Spielmeyer juvenile type, and Kufs adult type. All except a few adult cases are autosomal recessive. The storage material in neuronal cytoplasm consists of two pigmented lipids, presumably ceroid and lipofuscin, which are cross-linked polymers of polyunsaturated fatty acids and have the property of autofluorescence. Mole has published a useful review of the genetics of these diseases and points out that at least eight gene loci are implicated, for six of which the mutation has been identified. All the infantile forms and one juvenile form of the disease are due to mutations affecting the lysosomal enzyme palmitoyl-protein thioesterase. Other lysosomal enzymes are abnormal in the remaining juvenile and in the adult forms.

In the Finnish form of the disease, infants from 3 to 18 months of age, after a normal period of development, undergo psychomotor regression with ataxia, hypotonia, and widespread myoclonus. There are retinal changes with extinction of the electroretinogram, slowing of the EEG with spike and slow-wave discharges, and eventually an isoelectric record. Within a few years these patients become blind, develop spastic quadriplegia and microcephaly, and succumb. In the Jansky-Bielschowsky type, the onset of symptoms is between 2 and 4 years, after normal or slightly retarded earlier development, with survival to 4 to 8 years of age. Usually the first neurologic manifestations are seizures (petit mal or grand mal) and myoclonic jerks evoked by proprioceptive and other sensory stimuli, including voluntary movement and emotional excitement. Incoordination, tremor, ataxia, and spastic weakness with lively tendon reflexes and Babinski signs, deterioration of mental faculties, and dysarthria proceed to dementia and eventually to mutism. In patients with relatively late onset, a progressive dementia is the cardinal manifestation. Visual failure may occur early in some cases because of retinal degeneration (of rods and cones) with pigmentary deposits, but in others vision is normal. The electroretinogram becomes isoelectric if vision is affected. Abnormal inclusions (translucent vacuoles) are seen in 10 to 30 percent of circulating lymphocytes, and azurophilic granules in neutrophils. High-voltage EEG spikes are induced by photic stimuli. Only in early-onset cases is there microcephaly.

Pathologic examination shows neuronal loss in the cerebral and cerebellar cortices (granule and Purkinje cells), and curvilinear storage particles and osmophilic granules are visible in the remaining neurons. Inclusions are also observed in cutaneous nerve twigs and endothelial cells of blood vessels, findings which permit diagnosis during life by electron microscopy of skin, conjunctival, or rectal mucosal biopsies. In many patients with lipofuscinoses, diagnosis can be confirmed by demonstrating the presence of one or several recently identified gene mutations. There are no definite markers for the group in blood or urine, but in some patients a structural component of mitochondria is excreted in excess (the so-called C-fragment). In the differential diagnosis, one must consider late infantile GM, gangliosidosis, idiopathic epilepsy, Alpers disease, and other forms of neuronal ceroid-lipofuscinosis. The lipofuscinoses of later onset—the Vogt-Spielmeyer (juvenile) type and the Kufs (adult) type—are discussed further on. There is no treatment for the basic disease process, but approaches involving gene therapy are being explored.

Mucopolysaccharidoses (Table 37-7)

This is a group of diseases in which the storage of lipid in neurons is combined with that of polysaccharides in connective tissues. As a consequence there is a conjunction of neurologic and skeletal manifestations. Visual failure may occur early in some cases because of retinal degeneration (of rods and cones) with pigmentary deposits, but in others vision is normal. The electroretinogram becomes isoelectric if vision is affected. Abnormal inclusions (translucent vacuoles) are seen in 10 to 30 percent of circulating lymphocytes, and azurophilic granules in neutrophils. High-voltage EEG spikes are induced by photic stimuli. Only in early-onset cases is there microcephaly.

Pathologic examination shows neuronal loss in the cerebral and cerebellar cortices (granule and Purkinje cells), and curvilinear storage particles and osmophilic granules are visible in the remaining neurons. Inclusions are also observed in cutaneous nerve twigs and endothelial cells of blood vessels, findings which permit diagnosis during life by electron microscopy of skin, conjunctival, or rectal mucosal biopsies. In many patients with lipofuscinoses, diagnosis can be confirmed by demonstrating the presence of one or several recently identified gene mutations. There are no definite markers for the group in blood or urine, but in some patients a structural component of mitochondria is excreted in excess (the so-called C-fragment). In the differential diagnosis, one must consider late infantile GM, gangliosidosis, idiopathic epilepsy, Alpers disease, and other forms of neuronal ceroid-lipofuscinosis. The lipofuscinoses of later onset—the Vogt-Spielmeyer (juvenile) type and the Kufs (adult) type—are discussed further on. There is no treatment for the basic disease process, but approaches involving gene therapy are being explored.

abnormalities that is virtually unique. The nervous system may also be involved secondarily as a result of skeletal deformities and thickening and hyperplasia of connective tissue at the base of the brain, leading to obliteration of the subarachnoid space and obstructive hydrocephalus or compression of the cerebral cord. The prevalence of mucopolysaccharides as a whole is approximately 1 per 8000 births, according to Meikle and colleagues. Depending on the degree of visceral-skeletal and neurologic changes, at least seven distinct clinical subtypes are recognized (see Table 37-7).

The basic abnormality is an enzymatic defect that prevents the degradation of acid mucopolysaccharides (now called glycosaminoglycans). They can be measured and are increased in serum, leukocytes, or cultured fibroblasts. The storage is, again, within lysosomes in the brain, spinal cord, heart, viscerum, bone, and connective tissue. All forms of the disease except the Hunter syndrome, which is sex-linked, are inherited in an autosomal recessive pattern. The studies of Neufeld and Muenzer indicate that each type of mucopolysaccharidosis is caused by a defect in a different enzyme.

**Hurler Disease** This, the classic form, also known as MPS I, begins clinically toward the end of the first year. *Mental retardation* is severe, and *skeletal abnormalities* are prominent (dwarfism; gargoyliform facies; large head with synostosis of longitudinal suture; kyphosis; broad hands with short, stubby fingers; flexion contractures at knees and elbows). Conductive deafness and corticospinal signs are usually present. Proterubent abdomen, hernias, *enlarged liver and spleen*, valvular heart disease, chronic rhinitis, recurrent respiratory infections, and *corneal opacities* complete the picture. The biochemical abnormalities consist of the accumulation of *dermatan and heparan sulfate* (glycosaminoglycans) in the tissues and their excretion in the urine, due probably to absence of activity of **α-L-iduronidase**. Also, there is an increase in the ganglioside content in nerve cells of the brains of these patients. In the milder Scheie (MPS V) variant of Hurler disease, intelligence and life span are normal.

**Treatment** Enzyme replacement therapy (laronidase) is now becoming available. The enzymes are produced with recombinant technology and are successful where previous attempts with enzymes delivered by white cell or other infusions had been ineffective. Also being studied is hematopoietic stem cell bone marrow transplantation (cord blood from unrelated donors is used most often; see Staba et al). In order to be effective, treatment must commence before the accumulation of glycosaminoglycans and neurologic decline. The eye and bone deterioration associated with Hurler disease is not improved. In children with the milder Scheie form and those with CNS involvement, bone marrow transplantation is not helpful and enzyme replacement is recommended. Enzyme treatment is also being tried concurrently with bone marrow transplantation in early cases. These approaches have not been effective in the Hunter or the Sanfilippo diseases, discussed below.

**Sanfilippo Disease** This form, or MPS III, expresses itself clinically between 2 and 3 years of age, with progressive intellectual deterioration. The patients are of short stature, but in other respects the physical changes are fewer and less severe than in the Hunter and Hurler syndromes. Three and possibly four types of Sanfilippo disease, designated A, B, C, and D, are distinguished on the basis of their enzymatic defects (Neufeld and Muenzer). All subtypes are phenotypically similar, and all of them may excrete excessive amounts of heparan sulfate in the urine.

**Morquio Disease** This form of the disease, MPS IV, is characterized by marked *dwarfism* and *osteoporosis*. Skeletal deformity and compression of the spinal cord and medulla are constant threats, because of hypoplasia of the odontoid process and atlantoaxial dislocation and thickening of the dura around the cervical cord and inferior surface of the cerebellum. Intelligence is affected only slightly or not at all. *Corneal opacities may be present*. Patients excrete large amounts of keratan sulfate in the urine; two types of enzymatic deficiency have been identified (Neufeld and Muenzer).

**Maroteaux-Lamy Disease** This syndrome, MPS VI, includes severe skeletal deformities (short stature, anteriorly beaked vertebrae) but *normal intelligence*. Several patients observed by our colleagues have had a cervical pachymeningitis with spinal cord compression and hydrocephalus during adult life. Spinal cord function improved with cervical decompression and the hydrocephalus with ventriculocisternal shunting (Young et al). Hepatosplenomegaly is often present. Large amounts of dermatan sulfate are excreted in the urine, as a result of an *arylsulfatase B* deficiency.

**β-Glucuronidase Deficiency (Sly Disease)** This (MPS VII) is a rare type of mucopolysaccharidosis, the clinical features of which have yet to be sharply delineated. Short stature, progressive thoracolumbar gibbus, hepatosplenomegaly, and the bony changes of dysostosis multiplex (as in the Hunter type) are the main clinical features. There is excessive excretion of dermatan and heparan sulfate, the result of a deficiency of β-glucuronidase. Attempts to treat the mucopolysaccharidoses by enzyme replacement therapy, bone marrow transplantation, and gene transfer are in progress. None of these are far enough along to determine their efficacy.

**Mucolipidoses and Other Diseases of Complex Carbohydrates (Sialidoses; Oligosaccharidoses—Table 37-3)**

In recent years several new diseases have been described in which there is an abnormal accumulation of mucopolysaccharides, sphingolipids, and glycolipids in visceral, mesenchymal, and neural tissues, due to an α-N-acetylgalactosaminidase defect. In some types there is an additional deficiency of β-galactosidase. All are autosomal recessive diseases that manifest many of the clinical features of Hurler disease, but—in contrast to the mucopolysaccharidoses—normal amounts of mucopolysaccharides are excreted in the urine. Frequently, GM1 gangliosidosis, described above, is also classified with the mucolipidoses. The other members of this category are synopsized below and in Table 37-3.

**Mucolipidoses** At least three and possibly four closely related forms have been described. In mucolipidosis I (lipomucopolysaccharidosis), the morphologic features are those of gargoylism, with
slowly progressive mental retardation. Cherry-red spots in the maculae, corneal opacities, and ataxia have been noted in some patients. Vacuolation of lymphocytes, marrow cells, hepatocytes, and Kupffer cells in the liver and metachromatic changes in the sural nerve have been described.

In mucolipidosis II ("I-cell" disease), the most common of the mucolipidoses, there is usually an early onset of psychomotor retardation, but in some cases this does not appear until the second or third decade. Abnormal facies and periosteal thickening (dysoxosis multiplex, like that of GM1 gangliosidosis and Hurler disease) are characteristic. Gingival hyperplasia is prominent, and the liver and spleen are enlarged; but deafness is not found and corneal opacities are slower to develop. Tonic-clonic seizures are frequent in older patients. In most cases, death from heart failure occurs by the third to eighth year. There is a typical vacuolation of lymphocytes, Kupffer cells, and cells of the renal glomeruli. Bone marrow cells are also vacuolated and contain refractile cytoplasmic granules (hence the designation inclusion-cell, or I-cell, disease). A deficiency of several lysosomal enzymes required for the catabolism of mucopolysaccharides, glycolipids, and glycoproteins have been found.

In mucolipidosis III (pseudo-Hurler polydystrophy), the biochemical abnormalities are like those of I-cell disease, but there are clinical differences. In the pseudo-Hurler type, symptoms do not appear until 2 years of age or later and are relatively mild. Retardation of growth, fine corneal opacities, and valvular heart disease are the major manifestations.

Yet another variant, so-called mucolipidosis IV, has been described (see Tellez-Nagel et al). Here, clouding of the corneas is noticed soon after birth, and profound developmental retardation is evident by 1 year of age. Skeletal deformities, enlargement of liver and spleen, seizures, or other neurologic abnormalities are notably lacking. Ultrastructural examination of conjunctival and skin fibroblasts has demonstrated lysosomal inclusions of material similar to lipids and mucopolysaccharides that remain to be further characterized.

Mannosidosis This is another rare hereditary disorder with poorly differentiated symptomatology. The onset is in the first 2 years, with Hurler-like facial and skeletal deformities, mental retardation, and slight motor disability. Corticospinal signs, loss of hearing, variable degrees of gingival hyperplasia, and spoke-like opacities of the lens (but no diffuse corneal clouding) may be present. The liver and spleen are enlarged in some cases. Radiographs show beaking of the vertebral bodies and poor trabeculation of long bones. Vacuolated lymphocytes and granulated leukocytes are present and aid in diagnosis. The urinary mucopolysaccharides are normal. Mannosiduria is diagnostic, caused by a defect in α-mannosidase. Mannose-containing oligosaccharides accumulate in nerve cells, spleen, liver, and leukocytes (see Kistler et al).

Fucosidosis This also is a rare autosomal recessive disorder, with neurologic deterioration beginning usually at 12 to 15 months and progressing to spastic quadriplegia, decerebrate rigidity, severe psychomotor regression, and death within 4 to 6 years. Hepatomegaly, splenomegaly, enlarged salivary glands, thickened skin, excessive sweating, normal or typical gargoyl facies, beaking of the vertebral bodies, and vacuolated lymphocytes are the main features. A variant of this disease has been described with slower progression and survival into late childhood and adolescence and even into adult life (Ikeda et al). The latter type is characterized by mental and motor retardation, along with the corneal opacities, coarse facial features, skeletal deformities of gargoylism, and dermatologic changes of Fabry disease (angiokeratoma corporis diffusum), but no hepatosplenomegaly. The basic abnormality in both types is a lack of lysosomal L-fucosidase, resulting in accumulation of fucose-rich sphingolipids, glycoproteins, and oligosaccharides in cells of the skin, conjunctivae, and rectal mucosa.

Aspartylglycosaminuria This disease is characterized by the early onset of psychomotor regression; delayed, inadequate speech; severe behavioral abnormalities (bouts of hyperactivity) mixed with apathy and hypoactivity or psychotic manifestations; progressive dementia; clumsy movements; corticospinal signs; corneal clouding (rare); retinal abnormalities and cataracts; coarse facies including low bridge of the nose, epicanthi, thickening of the lips and skin; enlarged liver; and abdominal hernias in some. Radiographs show minimal beaking of the vertebral bodies, and the blood lymphocytes are vacuolated.

The pattern of inheritance in this entire group of diseases, as already stated, is probably autosomal recessive. Diagnostic methods applicable to amniotic fluid and cells are being developed so that prenatal diagnosis will be possible, prompted often by the occurrence of the disease in an earlier child. Neurons are vacuolated rather than stuffed with granules, much like the lymphocytes and liver cells. The specific biochemical abnormalities, as far as they are known, are listed in Table 37-3.

Cockayne Syndrome

This disorder is probably inherited as an autosomal recessive trait. The onset is in late infancy, after apparently normal earlier development. The main clinical findings are stunting of growth, evident by the second and third years; photosensitivity of the skin; microcephaly; retinitis pigmentosa, cataracts, blindness, and pendular nystagmus; nerve deafness; delayed psychomotor and speech development; spastic weakness and ataxia of limbs and gait; occasionally athetosis; amyotrophy with abolished reflexes and reduced nerve conduction velocities; wizened face, sunken eyes, prominent nose, prognathism, anhidrosis, and poor lacrimation (resembling progeria and bird-headed dwarfism). Some cases show calcification of the basal ganglia. The CSF is normal, and there are no diagnostic biochemical findings.

Pathologic examination reveals a small brain, striatal and cerebellar calcifications, leukodystrophy like that of Pelizaeus-Merzbacher disease, and a severe cerebellar cortical atrophy. The peripheral nerve changes are those of a primary segmental demyelination.

It is now apparent that Cockayne syndrome, like ataxia-telangiectasia, is a consequence of mutations in genes that mediate DNA repair. At least three different forms of Cockayne syndrome have been identified, each with a different underlying gene defect.

Rett Syndrome

This syndrome is mentioned here because for many years, on the basis of psychomotor regression after a period of normal development, it was presumed to have a metabolic basis (urea cycle defect). However, neither this metabolic defect nor any other has ever been substantiated. Recently, the responsible gene mutation has been discovered. The syndrome is discussed fully in Chap. 38, with other forms of developmental mental retardation and autism.
Other Diseases of Late Infancy and Early Childhood

Globoid cell leukodystrophy (Krabbe), subacute necrotizing encephalomyelopathy (Leigh), and Gaucher disease may also begin in late infancy or early childhood. They have been described in the preceding section of this chapter. Familial striatocerebellar calcification (Fahr disease) and Lesch-Nyhan disease may also become manifest in this age period, but they usually have a later onset and are therefore described with the diseases of later childhood in the section that follows.

Diagnosis of Metabolic Diseases of Late Infancy and Early Childhood

This group of metabolic disorders presents many of the same diagnostic problems as those of early infancy. The flow chart in Figure 37-4, which divides these disorders into dysmorphic, visceral/organic, and purely neurologic groups, is equally serviceable in the differential diagnosis of both age groups. As with the early infantile diseases, certain clusters of neurologic, skeletal, dermal, ophthalmic, and laboratory findings are highly distinctive and often permit the identification of a particular disease. These signs are listed below:

1. Evidence of involvement of peripheral nerves (weakness, hypotonia, areflexia, sensory loss, reduced conduction velocities) in conjunction with lesions of the CNS—
   a. Metachromatic leukodystrophy, Krabbe leukodystrophy, neuroaxonal dystrophy, and Leigh disease (rare)
2. Ophthalmic signs
   a. Corneal clouding—several of the mucopolysaccharidoses (Hurler, Scheie, Morquio, Maroteaux-Lamy), mucolipidoses, tyrosinemia, aspartylglycosaminuria (rare)
   b. Cherry-red macular spot—GM1 gangliosidosis, GM2 gangliosidosis (half the cases), lipomucopolysaccharidosis, occasionally Niemann-Pick disease
   c. Retinal degeneration with pigmented deposits—
      Jansky-Bielschowsky lipid storage disease, GM1 gangliosidosis, syndrome of sea-blue histiocytes
   d. Optic atrophy and blindness—metachromatic leukodystrophy, neuroaxonal dystrophy
   e. Cataracts—Marinesco-Sjögren syndrome, Fabry disease, mannosidosis
   f. Ocular apraxia—ataxia-telangiectasia, Niemann-Pick disease
   g. Impairment of vertical eye movements—late infantile Niemann-Pick disease, juvenile dystonic lipidosis, sea-blue histiocyte syndrome, Wilson disease
   h. Jerky eye movements, limited abduction—late infantile Gaucher disease
4. Extrapyramidal signs—late-onset Niemann-Pick disease (rigidity, abnormal postures), juvenile dystonic lipidosis (dystonia, choreoathetosis), Rett, ataxia-telangiectasia (atetosis), Sanfilippo mucopolysaccharidosis, type I glutaric acidemia, Wilson disease, Segawa dopa-responsive dystonia
5. Facial dysmorphism—Hurler, Scheie, Morquio, and Maroteaux-Lamy forms of mucopolysaccharidosis, aspartylglycosaminuria, mucolipidoses, GM1 gangliosidosis, mannosidosis, fucosidosis (some cases), multisulfatase deficiencies (Austin), some mitochondrial disorders
6. Dwarfism, spine deformities, arthropathies—Hurler, Morquio, and other mucopolysaccharidoses, Cockayne syndrome
7. Enlarged liver and spleen—Niemann-Pick disease, Gaucher disease, all mucopolysaccharidoses, fucosidosis, mucolipidoses, GM1 gangliosidosis
8. Alterations of skin—photosensitivity (Cockayne syndrome and one form of porphyria); papular nevi and angiookeratoma (Fabry disease, fucosidosis); telangiectasia of ears, conjunctiva, chest (ataxia-telangiectasia); ichthyosis (Sjögren-Larsen disease, caused by fatty alcohol dehydrogenase deficiency); plaque-like lesions in Hunter syndrome
9. Beaked thoracolumbar vertebrae—all mucopolysaccharidoses, mucolipidoses, mannosidosis, fucosidosis, aspartylglycosaminuria, multiple sulfatase deficiencies
10. Deafness—mucopolysaccharidoses, mannosidosis, Cockayne syndrome
11. Hypertrophied gums—mucolipidoses, mannosidosis
12. Vacuolated lymphocytes—all mucopolysaccharidoses, mucolipidoses, mannosidosis, fucosidosis
13. Granules in neutrophils—all mucopolysaccharidoses, mucolipidoses, mannosidosis, fucosidosis, multiple sulfatase deficiencies

In our experience the most difficult diagnostic problems in this age period are raised by neuroaxonal dystrophy, metachromatic leukodystrophy, the mitochondrial disorder subacute necrotizing encephalomyelopathy (Leigh disease), some cases of lipofuscinosis, and the late form of GM1 gangliosidosis. In none of these diseases is the clinical picture entirely stereotyped. Most helpful in the clinical diagnosis of neuroaxonal dystrophy is the onset, at 1 to 2 years of age, of severe hypotonia with retained reflexes and Babinski signs, early visual involvement without retinal changes, lack of seizures, normal CSF, physiologic evidence of denervation of muscles, fast-frequency EEG, normal CT scan, and N-acetyl-galactosaminidase deficiency in cultured fibroblasts. Metachromatic leukodystrophy can be excluded if the CSF protein is normal and if nerve conduction velocities and enzymatic studies of leucocytes and fibroblasts are normal. Similar criteria enable one to rule out GM1 gangliosidosis. Leigh disease may begin at the same age, with hypotonia and optic atrophy, but abnormalities of ocular movement and respiration appear early; in many cases the lactic acidosis and pyruvate decarboxylase defect will corroborate the diagnosis. Sequencing tests of the mitochondrial genome now allow definitive diagnosis in most cases, as described in a later section. Also in Leigh disease, CT scanning and MRI may disclose hypodense lesions in the basal ganglia and brainstem, in contrast to the normal CT scan in neuroaxonal dystrophy. In metachromatic leukodystrophy, the cerebral white matter shows a diffusely decreased attenuation and the MR images are striking (Fig. 37-6). Lipofuscinosis cannot always be diagnosed accurately; curvilinear bodies in nerve twigs and in the endothelial cells in skin biopsies and the recently discovered gene mutations are the most informative laboratory tests.

INHERITED METABOLIC ENCEPHALOPATHIES OF LATE CHILDHOOD AND ADOLESCENCE

Unavoidably, one must refer here to certain inherited metabolic diseases already described that permit survival into late childhood.
and adolescence as well as to diseases that begin in adolescence or adult life after a normal childhood. There is a tendency for them to be less severe and less rapidly progressive, an attribute shared by many diseases with a dominant mode of inheritance. Nonetheless, there are diseases, such as Wilson disease, in which the onset of neurologic symptoms occurs after the 10th year and in rare instances after the 30th year, and the mode of inheritance is recessive in type. However, in the latter instance, the basic abnormality has existed since early childhood in the form of a ceruloplasmin deficiency with early cirrhosis and splenomegaly; only the neurologic disorder is of late onset. This brings us to another principle—that the pathogenesis of the cerebral lesion may involve a factor or factors once removed from the underlying biologic abnormality.

Genetic heterogeneity poses another problem with respect to both the clinical and biochemical findings. It is well established that a single clinical phenotype such as the one seen in Hurler disease can be the expression of a number of different alleles of a given gene mutation. Conversely, a number of different clinical phenotypes may be based on different degrees of the same enzyme deficiency. One must, therefore, not rely solely on clinical appearance for diagnosis but always combine them with biochemical tests and molecular genetic studies for confirmation. No one of these lines of data, including genomics, is sufficient for classification of disease.

The diseases in this category are probably of greater interest to neurologists than the preceding ones, for they more consistently cause familiar neurologic abnormalities such as epilepsy, polymyoclonus, dementia, cerebellar ataxia, choreoathetosis, dystonia, tremor, spastic-ataxic paraparesis, blindness, deafness, and stroke. These manifestations appear much the same in late childhood and adolescence as they do in adult life, and the neurologist whose experience has been mainly with adult patients feels quite comfortable with them.

Diseases in this age period have a diversity of manifestations, yet each disease tends to have a certain characteristic pattern of neurologic expression, as though the pathogenetic mechanism were acting more selectively on particular systems of neurons. Such affinities between the disease process and certain anatomic structures raise the question of pathoclisis, i.e., specific vulnerability of particular neuronal systems to certain morbid agents. Stated another way, for each disease there is a common and relatively stereotyped clinical syndrome and a small number of variants; conversely, certain other symptoms and syndromes are rarely observed with a given disease. At the same time, however, it is clear that more than one disease may cause the same syndrome.

In deference to these principles, the diseases in this section are grouped according to their most common mode of clinical expression, as follows:

1. The progressive cerebellar ataxias of childhood and adolescence
2. The familial polymyoclonias and epilepsies
3. Extrapyramidal syndromes of parkinsonian type
4. The syndrome of dystonia and generalized choreoathetosis
5. The syndrome of bilateral hemiplegia, cerebral blindness and deafness, and other manifestations of focal cerebral disorder
6. Strokes in association with inherited metabolic diseases
7. Metabolic polyneuropathies
8. Personality changes and behavioral disturbances as manifestations of inherited metabolic diseases

It is advantageous to be familiar with these groupings, for a knowledge of them, like the age of onset and gray and white matter distinctions in diseases of earlier onset, facilitates clinical diagnosis. Variants seen personally by the authors are mentioned in the descriptions of the diseases themselves. One word of caution—it is a mistake to assume that the diseases in these categories affect one and only one particular part of the nervous system or to assume that they are exclusively neurologic. Once the biochemical abnormality is discovered, it is usually found to implicate cells of certain nonneurologic tissues as well; whether or not the effects of such involvement become symptomatic is often a quantitative matter. Also, one encounters mixed neurologic syndromes in which tremor, myoclonus, cerebellar ataxia, and choreoathetosis are present in various combinations; it is then difficult to decide whether a movement disorder is of one type or another.

The Progressive Cerebellar Ataxias of Late Childhood and Adolescence

In the preceding section it was pointed out that there is a large group of diseases, some with (but most without) a known metabolic basis, in which an acute, episodic, or chronic cerebellar ataxia becomes manifest in early childhood. Here the discussion of the cerebellar ataxias is continued, with reference to those forms that begin in late childhood and adolescence. In these later age periods the number of ataxias of proven metabolic type diminishes markedly. Most of them, of chronic progressive type, are part of the late-onset lipid storage diseases. Of the other cerebellar ataxias of late childhood and adolescence, only the Bassen-Kornzweig acanthocytosis and a genetic fault in vitamin E metabolism fall into the category of a truly metabolic disease—and one could perhaps add late-onset GM1 gangliosidosis, Refsum disease, and ataxia-telangiectasia. Refsum disease is so clearly a polyneuropathy (cerebellar features only in exceptional cases) that it is presented in Chap. 46. Ataxia-telangiectasia is usually encountered in late childhood, but the ataxia may begin as early as the second year of life; therefore it has been described in the preceding section with the ataxias of early childhood. An account of the effect of vitamin E deficiency on the nervous system is presented on page 997.

There are many other conditions of metabolic type in which cerebellar ataxia figures in the clinical picture. Some of these are associated with polymyoclonus and cherry-red macular spots (mainly sialidosis or neuraminidosis; see below). Cerebellar ataxia is a prominent feature of Unverricht-Lundborg (Baltic) disease and Lafora-body disease (Chap. 16). The Cockayne syndrome and Marinesco-Sjögren disease, already described under “Inherited Metabolic Diseases of Late Infancy and Early Childhood,” persist into later childhood and adolescence or may even have their onset in this later period. In cerebrotendinous xanthomatosis (see further on), spastic weakness and pseudobulbar palsy are combined with cerebellar ataxia. Prader-Willi children have a broad-based gait and are clumsy in addition to being obese, genetically deficient, and diabetic. One family of five males with a syndrome of hyperuricemia, spinocerebellar ataxia, and deafness has been reported by Rosenberg and colleagues, and several other variants of defective pyrimidine metabolism fit into this category; the enzymatic defect of Lesch-Nyhan disease was not present, however. Marsden and coworkers have observed cerebellar ataxia beginning in late childhood, as an expression of adrenoleukodystrophy (see below). The familial syndrome of neuropathy, ataxia, and retinitis pigmentosa (NARP, page 844) caused by a mitochondrial genome muta-
tion that impairs ATP synthase can closely mimic the Marinesco-Sjögren syndrome.

Doubtless, many of the progressive forms of cerebellar ataxia now classified as degenerative and described in Chap. 39 will be proved to have an underlying biochemical or similar subcellular pathogenesis and will logically fall in place here, with the metabolic diseases. At present, when faced with a progressive ataxia of cerebellar type even in a young adult, the reader should consult both this chapter and Chap. 39.

The acute forms of cerebellar ataxia that occur in late childhood and adolescence are essentially nonmetabolic, being traceable to postinfectious encephalomyelitis (page 641) or to postanoxic, postmenigitic, or posthyperthermic states and certain drug intoxications. With relatively pure cerebellar ataxias of this age period, postinfectious cerebellitis, cerebellar tumors (medulloblastomas, astrocytomas, hemorrhagictomas, and ganglioneuromas of Lhermitte-Duclos) should be considered in the differential diagnosis. MRI establishes the correct diagnosis.

**Bassen-Kornzweig Acanthocytosis (Abetalipoproteinemia)**

This disease, first described by Bassen and Kornzweig in 1950, excited great interest, for it gave promise of a breakthrough into a hitherto obscure group of “degenerative” disorders. In the 15-year period that followed the original report, less than a dozen cases were recorded, and several of the reports were based on the study of the same case. In our experience, it is a rare disease; we have seen only four cases. The resemblance to Friedreich ataxia is not so close that an experienced clinician would be likely to confuse the two.

The inheritance of this disease is autosomal recessive. The initial symptoms, occurring between 6 and 12 years (range, 2 to 20 years), are weakness of the limbs with areflexia and an ataxia of sensory (tabetic) type, to which a cerebellar component is added later (see also page 1158). Steatorrhea, raising the suspicion of celiac disease (sprue), often precedes the weak, unsteady gait. Later, in more than half the patients, vision may fail because of retinal degeneration (similar to retinitis pigmentosa). Kyphoscoliosis, pes cavus, and Babinski signs are other elements in the clinical picture. The neurologic disorder is relatively slowly progressive—by the second to third decade, the patient is usually bedridden.

The diagnostic laboratory findings are spiky or thorny red blood cells (acanthocytes), low sedimentation rate, and a marked reduction in the serum of low-density lipoproteins (cholesterol, phospholipid, and β-lipoprotein levels are all subnormal). Pathologic study has revealed the presence of foamy, vacuolated epithelial cells in the intestinal mucosa (causing absorption block); diminished numbers of myelinated nerve fibers in sural nerve biopsies, depletion of Purkinje and granule cells in all parts of the cerebellum; loss of fibers in the posterior columns and spino cerebellar tracts; loss of anterior horn and retinal ganglion cells and of muscle fibers and fibrosis of the myocardium. It has been proposed that the basic defect is an inability of the body to synthesize the proteins of cell membranes because of the impaired absorption of fat through the mucosa of the small intestine. Vitamin E deficiency may be a pathogenic factor, since the administration of a low-fat diet and high doses of vitamins A and E may prevent progression of the neurologic disorder, according to Illingworth and colleagues.

Often mentioned in the context of acanthocytosis is another rare condition, the McLeod syndrome, in which are combined heterogeneous combinations of progressive muscular atrophy, seizures, involuntary movements, and elevated serum CK. The acanthocytosis in this disease is the result of an abnormality of the red cell surface Kell antigen (Kx, coding for the protein called XK).

**Familial Hypobetalipoproteinemia**

This is a well-defined disease, resembling abetalipoproteinemia, in which there is hypocholesterolemia, acanthocytosis of red blood corpuscles, retinitis pigmentosa, and a pallidal atrophy (so-called HARP syndrome). Inheritance is autosomal dominant, and heterozygotes may exhibit some part of the syndrome. Many cases are caused by mutations in the gene encoding beta-lipoprotein B. Fat droplets may be seen in the jejunal mucosa, indicating malabsorption. Cases have been reported from Europe, Asia, and the United States. Treatment consists of restriction of dietary fat and supplements of vitamin E.

An adult form of acanthocytosis associated with hereditary chorea and dystonia has also been recognized, but evidence of lipid malabsorption is lacking. This disease is described in Chap. 39.

**Hereditary Paroxysmal Cerebellar Ataxia**

This not uncommon syndrome of periodic ataxia, akin to the familial paroxysmal choreoathetosis and periodic dystonia described in Chap. 4, is inherited as an autosomal dominant trait. The gene for hereditary paroxysmal ataxia codes for a subunit of the calcium channel. It has its onset in childhood or early adult life and takes the form of disabling episodic attacks of ataxia, nystagmus, and dysarthria, each attack lasting a few minutes or a few hours. Between attacks the patients are asymptomatic or show only a mild nystagmus or minimal clumsiness. The remarkable feature is the prevention of attacks by the administration of acetazolamide, 250 mg thrice daily, as noted originally by Griggs et al. These characteristics apply to what is now termed familial episodic ataxia type 2. The rarer type 1 is related to a mutation in the voltage-gated potassium channel and is associated with myokymia and epilepsy.

**The Familial Polymyoclonias**

As stated in Chap. 6, the term myoclonus is applied to many conditions that are not at all alike but share a single clinical feature—a multitude of exceedingly brief, random, arrhythmic twitches of parts of muscles, entire muscles, or groups of muscles. Myoclonic jerks differ from chorea by virtue of their brevity (15 to 50 ms). Notably, both phenomena are considered to be symptomatic of “gray matter” diseases (“polioencephalopathies”).

Myoclonus or polymyoclonus may, in certain conditions, stand alone as a relatively pure syndrome. In other cases, it is mixed with epilepsy or atetosis and dystonia, discussed further on. Most often, myoclonus is associated with cerebellar ataxia; it is therefore being considered here, with the progressive cerebellar ataxies. The many acquired forms of polymyoclonus, such as subacute sclerosing panencephalitis, have been mentioned in Chap. 6. In this chapter we are concerned only with those of known or presumed metabolic origin.

**Myoclonic Encephalopathy of Infants (Infantile Opsoclonus-Myoclonus Syndrome)**

Under this title Kinsbourne originally described a form of widespread, continuous myoclonus (except during deep sleep) affecting male and female infants whose development had been normal until the onset of the disease at the age of 9 to 20 months. The myoclonus evolves over a week or less, affects all the muscles of the body, and interferes seriously with all the natural muscular activities of the child. The eyes are notably affected by rapid (up to eight per second), irregular conjugate
movements ("dancing eyes" of an opsoclonic type). The child is irritable and speech may cease. All laboratory tests are normal.

**Treatment** Adrenocorticotropic hormone and dexamethasone, the latter in doses of 1.5 to 4.0 mg/day, suppress the myoclonus and permit developmental progress. Some patients have recovered from the myoclonus but have been left mentally slow and mildly ataxic. Others have required corticosteroid therapy for 5 to 10 years, with relapse whenever it was discontinued. Ordinary anticonvulsants seem to have no effect. The pathology has not been determined.

A similar syndrome has been observed in conjunction with neuroblastoma in children and as a transient illness of unknown cause (probably viral or postinfectious) in young adults (Baringer et al; see page 641). It is mentioned here because a similar condition is also known in adults, as a paraneoplastic disease with ovarian, breast, gastric, and bronchogenic carcinomas and with other occult tumors.

In a broader survey of the pediatric opsoclonus-myoclonus syndrome, Pranzatelli and associates reported their experience with 27 cases, some with neuro crest tumors, others with viral infections or hypoxic injury (intention myoclonus). In nearly all of their patients there was cerebellar ataxia and mental disorder, and 10 percent had seizures. The CSF was normal. The investigators have emphasized the pathogenetic heterogeneity and defined a rare serotoninergic type (low levels of 5-hydroxytryptophan and homovanillic acid in the CSF) that responds to 5-hydroxyindole acetic acid.

**Familial Progressive Myoclonus** Five major categories of familial polymyoclonus of late childhood and adolescence have been delineated: (1) Lafora- or amyloid-body type, (2) juvenile cerebroretinal degeneration, (3) cherry-red spot—myoclonus (sialidosis or neuraminidosis), (4) mitochondrial encephalopathy, and (5) a more benign degenerative disease (dyssynergia cerebellaris myoclonica of Hunt). Familial myoclonus may also be a prominent feature of two other diseases—GM1 gangliosidosis and Gaucher disease—which occasionally have their onset in this age period.

**Lafora-Body Polymyoclonus with Epilepsy** This disease, which is inherited as an autosomal recessive trait, was first identified by Lafora in 1911 on the basis of the large basophilic cytoplasmic bodies that were found in the dentate, brainstem, and thalamic neurons. These inclusions have been shown by Yokoi and colleagues to be composed of a glucose polymer (polyglycosan) that is chemically but not structurally related to glycerogen. Possibly some of the cases of familial myoclonus epilepsy reported by Unverricht and by Lundborg were of this type, but since these authors provided no pathologic data, one cannot be sure.

Beginning in late childhood and adolescence (11 to 18 years) in a previously normal individual, the disease announces itself by a seizure, a burst of myoclonic jerks, or both. In about half the cases there are focal (often occipital) seizures. The illness may at first be mistaken for ordinary epilepsy, but within a few months it becomes evident that something far more serious is occurring. The myoclonus becomes widespread and can be evoked as a startle by noise, an unexpected tactile stimulus (even the tap of a reflex hammer), and also by excitement, or certain sustained motor activities. An evoked train of myoclonic jerks may progress to a generalized seizure with loss of consciousness. As the disease advances, the myoclonus interferes increasingly with the patient’s motor activities until voluntary function is seriously impaired. Speech may be marred, much as it is in chorea. Close examination may also reveal an alteration in muscle tone and a slight degree of cerebellar ataxia. At this time, or even before the onset of myoclonus and seizures, the patient may experience visual hallucinations or exhibit irritability, odd traits of character, uninhibited or impulsive behavior, and, ultimately, progressive failure in all cognitive functions. Deafness has been an early sign in a few cases. Rigidity or hypotonia, impaired tendon reflexes, acrocyanosis, and rarely corticospinal tract signs are late findings. Finally the patient becomes cachectic and bedfast and succumbs to intercurrent infection. Most do not survive beyond their 25th birthday. Nonetheless there are isolated reports of Lafora-body disease in which symptoms began as late as 40 years, with death as late as 50 years. These late cases may constitute a separate genetic type.

No abnormalities of the blood, urine, or CSF have been detected. The EEG shows diffuse slow waves and spikes as well as bursts of focal or multifocal discharges. Altered hepatocytes with homogeneous PAS-positive bodies that displace the nuclei have been observed in both the presymptomatic and symptomatic stages of the disease. These inclusions have been seen in skin and liver biopsies, even though liver function tests were normal. Neuropathologic examinations have shown a slight loss of granule and Purkinje cells and loss of neurons in the dentate nuclei, inner segment of globus pallidus, and cerebral cortex in addition to the Lafora bodies. The latter may also be seen in the retina, cerebral cortex, myocardium, and striated muscles. Anticonvulsant drugs, especially methsuximide and valproic acid, help in the control of the seizures but have no effect on the basic process.

**Polyglycosan Body Disease** (See also page 914) This is another closely related disease, the features of which have been reviewed by Robitaille and coworkers, in which glycosamine bodies are found in the central and peripheral nervous system. The clinical syndrome includes dementia, chorea, and amyotrophy with or without sensory loss in the limbs. Similar bodies are found in the cells of the liver and heart. This is a progressive disease usually beginning in adult life. It has been attributed to the accumulation of polymers of glucose. Diagnosis is confirmed by the finding of the polyglycosan bodies in the axons of peripheral nerves or liver cells. The causative mutation in most cases affects the gene for glycerogen branching enzyme.

**Juvenile Cereoid Lipofuscinosis (Cerebroretinal Degeneration)** As stated earlier, this is one of the most variable forms of the lipidoses. The salient clinical features of the later-onset types are severe myoclonus, seizures, and visual loss. In the juvenile type, the first lesions are seen in the maculae; they appear as yellow-gray areas of degeneration and stand in contrast to the cherry-red spot and the encircling white ring of Tay-Sachs disease. At first, the particles of retinal pigment are fine and dust-like; later they aggregate to resemble more the bone-corpuscular shapes of retinitis pigmentosa. The liver and spleen are not enlarged and there are no osseous changes. The usual development of these and other manifestations of the disease was outlined by Sjögren, who studied a large number of the late infantile and juvenile types of cases in Sweden. He divided the illness into five stages:

1. Visual impairment, sometimes preceding retinal changes by months.
2. After approximately 2 years, the onset of generalized seizures and myoclonus, often with irritability, poor control of emotions, and stuttering, jerky speech.
3. Gradual intellectual deterioration (poor memory, reduced mental activity, inattentiveness). By this stage the move-
ments have usually become slow, stiff, and tremulous, resembling somewhat those of Parkinson disease—to which are added elements of cerebellar ataxia and intention tremor, coming in this respect to resemble Wilson disease.

4. Stage of severe dementia in which the patient needs assistance to walk, no longer speaks, and may scream when disturbed or forced to move. The muscles are wasted, though the tendon reflexes remain lively, and the plantar reflexes are extensor.

5. Finally the patient lies curled up in bed, blind and speechless, with strong extensor plantar reflexes, occasionally adopting dystonic postures. Life usually ends in 10 to 15 years.

In the early stages the EEG picture of random, high-voltage, triphasic waves is diagnostic; later, as the seizures and myoclonic jerks become less frequent and finally cease, only delta waves remain. The electroretinographic waveforms are lost once the retina is affected. The lateral ventricles are slightly dilated in CT scans and on MRI. The CSF is normal. Diagnosis can be confirmed by the appearance of inclusions of a curvilinear “fingerprint” pattern in electron microscopic study of biopsy material, particularly of the eccrine sweat glands of the skin. A defective membrane protein has been identified that forms the inclusion material in the most common, or classic, juvenile phenotype. The genetics of the lipofuscinoses have been reviewed by Mole.

Late Juvenile and Adult Ceroid Lipofuscinosis (Kufs disease)

The Kufs type of ceroid lipofuscinosis, which develops later (15 to 25 years of age or older), is often unattended by visual or retinal changes and is even slower in its evolution. It is presented here for ease of exposition, but it becomes relevant mostly in relation to dementing illness in young adulthood (page 829). Personality change or dementia is one constellation, the other being myoclonic seizures with subsequent dementia and even later pyramidal and extrapyramidal signs. As the disease progresses, cerebellar ataxia, spasticity and rigidity or ataxiosis, or mixtures thereof, are combined with dementia. As a measure of the variability of the clinical presentation, a recent patient of ours had vague visual difficulties at age 51 and evolved a spastic quadriparesis with disinhibited behavior over 5 years. Further comments regarding the unusual presentations of this disease can be found further on, under “Adult Forms of Inherited Metabolic Disease.” van Bogaert pointed out to our colleague R. D. Adams that relatives of these patients may have retinal changes without neurologic accompaniments. The genetic defect for the adult form has been partially analyzed (see below).

Of all the lipidoses, these cerebroretinal degenerations had for decades defied unifying biochemical definition. Our understanding of these diseases is difficult because they embody both enzymatic defects and structural protein dysfunctions. In a few of the early childhood types, mutations of one of several lysosomal enzymes have been identified, as summarized by Mole and by Wisniewski and colleagues. As mentioned earlier, Zeman and coworkers have shown that the cytoplasmic inclusions are autofluorescent and give a positive histochemical reaction for both ceroid and lipofuscin, but this material is not different biochemically from the lipid substance that accumulates in aging cells. In addition to the presence of curvilinear bodies in the cytoplasm of neurons and other tissues, some in a fingerprint pattern, there is a reduction in type II synapses in the distal parts of the axon. All these changes precede nerve cell loss. The genetic defects have been tentatively determined for some of the subtypes of neuronal ceroid lipofuscinosis (see Wisniewski et al). These genes have been designated CLN 1 through 8, and they contain over 100 different mutations.

Childhood or Juvenile GM_2 Gangliosidosis Rarely, instances of the recessive type of GM_2 gangliosidosis have their onset at this age period. Twenty-four such cases (from 20 kindreds) were collected from the medical literature by Meek and coworkers. Ataxia and dystartria were frequently the presenting symptoms, followed by dementia, dysphagia, spasticity, dystonia, seizures, and myoclonus. Degeneration of anterior horn cells with progressive muscular atrophy may be a feature, although this is more characteristic of the adult-onset variety (see further on). Atypical cherry-red spots are observed in some patients. The biochemical abnormality, i.e., a deficiency of hexosaminidase A, is the same as in Tay-Sachs disease but not as severe or as extensive. Progression of the disease is slow, over a period of many years. One of our patients is alive at 50 years, the disease having begun in adolescence.

Late Gaucher Disease with Polymyoclonus A type of Gaucher disease is occasionally encountered in which seizures, severe diffuse myoclonus, supranuclear gaze disorders (slow saccades, saccadic and pursuit horizontal gaze palsy), and cerebellar ataxia begin in late childhood, adolescence, or adult life. The course is slowly progressive. The intellect is relatively spared. The spleen is enlarged. The pathologic and biochemical abnormalities are the same as those of Gaucher disease of earlier onset (Winkelman et al).

Cherry-Red Spot—Myoclonus Syndrome (Sialidase Type 1, α-Neuraminidase Deficiency) This is a relatively new and genetically distinct class of disease characterized by the storage in nervous tissue of sialilated glycopeptides. It is due to a neuraminidase deficiency. In some of the patients the onset has been in late childhood or adolescence and in others even later. In addition to the patients initially reported by Rapin and coworkers, 24 similar cases have appeared in the medical literature, and we have personally observed examples.

In the cases described by Rapin and colleagues and in two of our own, the first findings were visual impairment with cherry-red macular spots, similar to those seen in Tay-Sachs disease and less consistently in GM_2 gangliosidosis, Niemann-Pick disease, and metachromatic leukodystrophy. In one case there was severe episodic pain in the hands, legs, and feet during hot weather, reminiscent of Fabry disease. Polymyoclonus followed within a few years and, together with cerebellar ataxia, disabled the patients. Mental function remained relatively normal. Liver and spleen were not enlarged, but storage material was found in the Kupffer cells, neurons of the myenteric plexus, and cerebral neurons, presumably in cerebellar and retinal neurons.

The cases of Thomas and colleagues were young adults, all members of one generation, who had developed dystartria, intention myoclonus, cerebellar ataxia, and cherry-red macular lesions. Like the cases of Rapin and coworkers, the heredity was autosomal recessive. There was urinary excretion of sialilated oligosaccharides and a sialidase deficiency in cultured fibroblasts. The two patients described by Tsuji and associates are noteworthy in that they were aged 50 and 30 years, respectively. In addition to the macular lesions, polymyoclonus, and cerebellar ataxia, there were gargoyle-like facial features, corneal opacities, and vertebral dysplasia. These patients also had a neuraminidase (partial β-galactosidase) deficiency.
**Dentatorubral Cerebellar Atrophy with Polymyoclonus** This progressive degeneration of the cerebellar-dentatal efferent system was originally described by Ramsey Hunt under the title of *dys-synergia cerebellaris myoclonica*. The onset is in late childhood; both sexes are vulnerable, and it probably has more than one cause. In Hunt’s case, a progressive ataxia was accompanied by a striking degree of action myoclonus. Seizures are infrequent and the intellect is relatively preserved. The neurons of the dentate nuclei and their ascending and descending brainstem axons gradually disappear. Berkovic and associates have studied 84 cases of polymyoclonus, 13 of which conformed to the Hunt syndrome. Of these, 9 proved to have a mitochondrial encephalomyopathy. However, there are other reports (Tassinari et al) in which muscle biopsies showed no mitochondrial abnormalities. In the series of 30 cases reported by Marsden and coworkers, the onset was usually before the age of 21 years. Cortical electrographic discharges were found to precede each myoclonic twitch (cortical myoclonus). A biochemically supported diagnosis could not be made in nearly half of their cases.

We have observed restricted, extremely chronic forms of rhythmic myoclonus that involved only the facial and bulbar muscles. Although this benign familial polymyoclonia has not been associated with any biochemical abnormality, its association with cellular mitochondrial abnormalities in some cases justifies its inclusion in this chapter rather than with the degenerative diseases. Another mitochondrial disorder, the myoclonic epilepsy ragged red fiber (MERRF) disease, begins in the second decade or later with myoclonus and ataxia and enters into the differential diagnosis of this group of diseases. The mitochondrial diseases as a group are considered in the last part of this chapter.

**Epilepsies of Hereditary Metabolic Disease** (See Chap. 16)

Convulsive seizures may complicate nearly all hereditary metabolic diseases. The seizures may occur at all ages but more frequently in the neonate, infant, or young child than in the older child or adolescent. The seizures take many forms, as discussed in Chap. 16. Most often they are generalized grand mal or partial types; typical petit mal probably does not occur. Some diseases may cause focal seizures, simple or complex partial, before becoming generalized. The combination of series of polymyoclonic jerks progressing to a generalized motor seizure is always highly suggestive of one of the hereditary metabolic diseases. Another highly significant form of presentation is with sensory evoked seizures. The subject of epilepsy and the hereditary metabolic diseases has recently been reviewed by Sansaricq and colleagues.

**EXTRAPYRAMIDAL SYNDROMES WITH HEREDITARY METABOLIC DISEASE**

**Parkinsonian Syndromes**

Reference is made here to the distinctive extrapyramidal motor disorders described in Chap. 4. In the typical parkinsonian syndrome, with features of rigidity, tremor, and bradykinesia, strength remains relatively intact and corticospinal signs are absent, but effectiveness of movement is nonetheless impaired by the patient’s disinclination to use the affected parts (hypo- or akinesia), by slowness (bradykinesia), and by rigidity and tremor. Other clinical syndromes in this category include choreoathetosis, dystonia, and spasms of gage.

When the parkinsonian syndrome or some component thereof has its onset in middle or late adult life, it usually indicates idiopathic Parkinson disease or related multisystem forms of striatogniral degeneration. The development of such an extrapyramidal motor disorder in late childhood and adolescence instead suggests Wilson disease, Hallervorden-Spatz disease, and the Segawa type of L-dopa-responsive dystonia as well as other so-called Parkin mutations (see Chap. 39).

**Hepatolenticular Degeneration (Wilson Disease, Westphal-Strümpell Pseudosclerosis)** Wilson’s classic description of “Progressive lenticular degeneration: A familial nervous disease associated with cirrhosis of the liver” appeared in 1912. A similar neurologic disorder had been described previously by Gowers (1906) under the title of “tetanoid chorea” and by Westphal (1883) and Strümpell (1898), as “pseudosclerosis.” None of these authors, however, recognized the association with cirrhosis. The clinical studies of Hall (1921) and the histopathologic studies of Spielmeyer (1920), who re-examined sections from the liver and brain of Westphal’s and Strümpell’s cases, clearly established that the pseudosclerosis described by these authors was the same disease as the one that had been described by Wilson. Interestingly, none of these authors, including Wilson, noticed the golden-brown (Kayser-Fleischer) corneal ring, the one pathognomonic sign of the disease. The corneal abnormality was first described by Kayser in 1902, and in the following year Fleischer related it to pseudosclerosis. Rumpell had demonstrated the greatly increased copper content of the liver and brain as early as 1913, but this discovery was generally ignored until Mandelbrote (1948) found, quite by chance, that the urinary excretion of copper was greatly increased in patients with Wilson disease and that it was increased even more after the intramuscular administration of the chelating agent British antilewisite (BAL). In 1952, Scheinberg and Gitlin discovered that ceruloplasmin, the serum protein that binds copper, is reduced in this disease (see reviews by Scheinberg and Sternlieb for a full historical account and references). Denny Brown first demonstrated a recession of symptoms after prolonged treatment with BAL.

The prevalence of the disease cannot be stated exactly but is on the order of 1 per 50,000 to 1 per 100,000 of the general population. Siblings of a patient with Wilson disease have a 1 in 4 risk of developing the disease. The disease is transmitted as an autosomal recessive trait, and the abnormal gene resides on chromosome 13, in the region 13q14. One of the curious aspects of the genetics of the disease is the multitude of mutations within this gene that give rise to the disease, almost akin to an allelic variant at a normal site; and, no one mutation accounts for more than 30 percent of cases. The gene, called ATP7B (homologous with the ATP7A gene, which is defective in Menkes disease), codes for a membrane-bound, copper-binding ATPase. Inadequate functioning of this enzyme in some way reduces excretion of copper in the bile. As noted further on, liver transplantation halts progression of the disease, indicating that the primary biochemical effect of the mutation is in the liver rather than the nervous system.

The genetic defect gives rise to two fundamental disturbances of copper metabolism—a reduced rate of incorporation of copper into ceruloplasmin and a reduction in biliary excretion of copper. The deposition of copper in tissues is the cause of virtually all the manifestations of the disease—cirrhosis, hemolytic anemia, renal
tubular changes, Kayser-Fleischer rings, and, in all likelihood, the cerebral damage—as discussed below.

Clinical Features The onset of neurologic symptoms is usually in the second and less often in the third decade, rarely beyond that time. Half of patients are symptomatic by age 15, but exceptional cases, including two under our care, had their first clinical manifestations as late as their mid-fifties. In all instances the initial event is a deposition of copper in the liver, leading to an acute or chronic hepatopathy and eventually to multilobular cirrhosis and splenomegaly (Scheinberg and Sternlieb). In childhood, the liver disorder often takes the form of attacks of jaundice, unexplained hepatosplenomegaly, or hypersplenism with thrombocytopenia and bleeding. Rarely is there clear evidence of cirrhosis alone. The hepatic abnormalities may be asymptomatic (except for elevated serum transaminases), in which case the initial clinical presentation is neurologic. In some instances, a hemolytic anemia or, less often, renal tubular acidosis may first draw attention to the disease.

The first neurologic manifestations are most often extrapyramidal with a proclivity to affect the oropharyngeal musculature. The typical presentations are tremor of a limb or of the head and generalized slowness of movement (i.e., a parkinsonian syndrome); or slowness of movement of the tongue, lips, pharynx, larynx, and jaws, resulting in dysarthria, dysphagia, and hoarseness; or there may be slowness of finger movement and occasionally choreic movements or dystonic postures of the limbs. Often the mouth is held slightly open in the early stage of the disease. Exceptionally, an abnormality of behavior (argumentativeness, impulsiveness, excessive emotionality, depression, delusions) or a gradual impairment of intellectual faculties precedes other neurologic signs by a year or more (see Starosta-Rubinstein et al).

As the disease progresses, the “classic syndrome” evolves; dysphagia and drooling, rigidity and slowness of movements of the limbs; flexed limb postures; fixity of facial muscles with mouth constantly agape, giving an appearance of grinning or a “vacuous smile”; dysarthria or virtual anarthria (bulbar extrapyramidal syndrome); and a tremor in repose that increases when the limbs are outstretched to a coarse, “wing-heating” movement. Slowed saccadic eye movements and limitation of upgaze are also characteristic. A notable feature is the tendency for the motor disorders to be concentrated in the bulbar musculature and to spread caudally. Thus, the syndrome differs from classic parkinsonism. Usually elements of cerebellar ataxia and intention tremor of variable degree are added at some stage of the disease. Approximately 6 percent of patients develop seizures (Dening et al). Gradually the disability increases because of increasing rigidity and tremor. The patient becomes mute, immobile, extremely rigid, dystonic, and slowed mentally, the latter usually being a late and variable effect.

With progression of the neurologic disease, the Kayser-Fleischer rings become more evident (Fig. 37-7). They take the form of a crescentic rusty-brown discoloration of the deepest layer of the cornea (Descemet’s membrane). In the purely hepatic stage of the disease, the rings may not be evident (in 25 percent of cases), but they are invariably present once the neurologic signs become manifest. A slit-lamp examination may be necessary for their early detection, particularly in brown-eyed patients, but in the majority of patients with neurologic signs the rings can be visualized with the naked eye or with the aid of an indirect ophthalmoscope focused on the limbus.

The diagnosis is virtually certain when there is a similar syndrome in a sibling or when an extrapyramidal motor disorder of this type is conjoined with liver disease and the corneal rings. Variants of the above syndrome that the authors have seen are an early choreoathetosis (like Sydenham chorea); prominent dystonic postures; a cerebellar ataxia with minimal rigidity; a syndrome of coarse action or action and intention tremor resembling that of dentatorubral degeneration; an immobile mute state with profound rigidity; and a dementia, character change, or psychosis with relatively few extrapyramidal signs. Action myoclonus as a prominent early manifestation has also been described. The parkinsonian features do not respond to L-dopa treatment.

Laboratory Findings In both the typical and variant forms of the disease, the finding of a low serum ceruloplasmin level (less than 20 mg/dL in 80 to 90 percent of patients), low serum copper (3 to 10 mM/L; normal 11 to 24 mM/L), and increased urinary copper excretion (more than 100 mg Cu/24 h) corroborate the diagnosis. Because 90 percent of copper is carried by ceruloplasmin and the latter is generally reduced in Wilson disease, serum copper values alone may be misleadingly normal. Early in the course of the illness, the most reliable diagnostic findings are a high copper content in a biopsy of liver tissue (more than 200 mcg Cu/g dry weight) and a failure to incorporate labeled 64Cu into ceruloplasmin. The latter test, however, fails to dependably differentiate asymptomatic carriers from affected individuals. Measurement of increased copper excretion after the administration of penicillamine has not been shown to be more sensitive than an unenhanced 24-h urine collection for copper. Persistent aminoaciduria, reflecting a renal tubular abnormality, is present in most but not all patients. Liver function tests are usually abnormal; some patients are jaundiced and other signs of liver failure may appear late in the illness. In these patients, the serum ammonia may be elevated and the symptomatology may worsen with increases in dietary protein. The cirrhosis is not always evident in a liver biopsy (some regenerative nodules are large, and the biopsy may be taken from one of them). On the other hand, the diagnosis in children may be revealed when a liver biopsy is taken for the evaluation of cirrhosis. As mentioned earlier, the large number of mutations that give rise to the disease makes it impractical to use genetic analysis for diagnosis, but once the gene abnormality has been established in a given family, linkage studies may be used to identify other affected sibs.

It has been established that copper deposition in the liver is the initial disturbance; over time it leads to cirrhosis, so that, as already mentioned, the hepatic stage of the disease precedes neu-
neurologic involvement. Cranial CT scans are abnormal even in the hepatic stage and are invariably so when the neurologic disorder supervenes. The lateral ventricles and often the third ventricle are slightly enlarged, the cerebral and cerebellar sulci are widened, the brainstem appears shrunken, and the posterior parts of the lenticular nuclei, red nuclei, and dentate nuclei become hypodense (Ropper et al). With treatment, these radiologic changes become less marked (Williams and Walshe). MRI is an even more sensitive means of visualizing the structural changes, particularly those in the subcortical white matter, midbrain,pons, and cerebellum (Starosta-Rubinstein et al). In the MRI survey by Saatci and colleagues, the putamen was involved most frequently (though not invariably), showing a symmetrical T2 signal change in a laminar pattern; there was also an increase in T1 signal throughout the basal ganglia, particularly in the pallidum. Signal changes are almost universally found in the cauclastrum and also in the midbrain (pars compacta of the substantia nigra), dentate nucleus of the cerebellum,pons, and thalamus. We have been impressed with a glassy diffuse and confluent signal abnormality on T2-weighted and FLAIR images in the hemispherical white matter in some cases—findings that were mistaken for multiple sclerosis.

**Neuropathologic Changes** These vary with the rate of progress of the disease. Exceptionally, in the rapidly advancing and fatal form, there is frank cavitation in the lenticular (putaminal and pallidal) nuclei, as observed in Wilson’s original cases. In the more chronic form there is only shrinkage and a light-brown discoloration of these structures. Nerve cell loss and some degree of degeneration of myelinated fibers in lenticular nuclei, substantia nigra, and dentate nuclei are usually apparent. Subcortical myelin degeneration is found in some cases. More striking, however, is a marked hyperplasia of protoplasmic astrocytes (Alzheimer type II cells) in the cerebral cortex, basal ganglia, brainstem nuclei, and cerebellum, almost certainly a reaction to liver failure and hyperammonemia.

**Treatment** Ideally treatment should be started before the appearance of neurologic signs; if this can be effected, neurologic deterioration can be prevented to a large extent. Treatment consists of (1) reduction of dietary copper to less than 1 mg/day, which can usually be accomplished by avoidance of copper-rich foods (liver, mushrooms, cocoa, chocolate, nuts, and shellfish), and (2) administration of the copper chelating agent D-penicillamine (1 to 3 g/day) by mouth, in divided doses. Pyridoxine 25 mg/day should be added in order to prevent anemia. The use of D-penicillamine is associated with a number of problems. Sensitivity reactions to the drug (rash, arthralgia, fever, leukopenia) develop in 20 percent of patients and require a temporary reduction of dosage or a course of prednisone to bring them under control. Reinstitution of drug therapy should then be undertaken, using low dosages (250 mg daily) and, later, small, widely spaced increases. If the patient is still sensitive to D-penicillamine or if severe reactions (lupus-like or nephrotic syndromes) occur, the drug should be discontinued and another chelating agent, triethylene tetramine (trientine) or ammonium tetrathiomolybdate may be substituted. Zinc, which blocks the intestinal absorption of copper, is also a suitable treatment, but ineffective alone. It is given as zinc acetate, 100 to 150 mg daily in three to four divided doses at least 1 h before meals (Hoogenraad et al). The appropriate drug must then be continued for the patient’s lifetime. Some women report improvement in neurologic symptoms during pregnancy, although there is no apparent change in copper metabolism during this time. In most patients, neurologic signs improve in response to decoppering agents. The Kayser-Fleischer rings disappear and liver function tests may return to normal, although the abnormalities of copper metabolism remain unchanged. In moderately severe and advanced cases, clinical improvement may not begin for several months despite full doses of D-penicillamine, and it is important to resist discontinuing the drug during this latent period. One of our patients had a complete remission of severe neurologic symptoms with penicillamine treatment and has remained symptom-free for 30 years.

It is also well known that the institution of treatment with penicillamine may induce an abrupt worsening of neurologic signs, and we have witnessed several such instances, including one that culminated fatally from a cardiac arrhythmia. Furthermore, in many of these patients, the lost function is never retrieved. Presumably this deterioration may be due to the rapid mobilization of copper from the liver and its redistribution to the brain. The slow introduction of penicillamine may avoid this complication. The additional use of zinc or one of the newer agents mentioned above should be instituted as soon as neurologic deterioration becomes evident. In at least one reported case, new lesions of Wilson disease (shown by MRI) developed while the patient was receiving full doses of D-penicillamine and excellent decoppering of the liver had occurred (Brewer et al). In the few patients who develop epilepsy, the seizures may become apparent soon after therapy is begun.

Many Wilsonian patients with advanced liver disease have been subjected to liver transplantation, which is curative for the underlying metabolic defect. The degree of neurologic improvement varies; in some it has been remarkable and sustained, confirming that the hepatic defect is primary and that the brain is involved secondarily. According to Schilsky and coworkers, the main indication for transplantation is severe and progressive liver damage, but the operation has been used successfully in some patients with intractable neurologic deterioration and only mild signs of liver disease.

An important aspect of treatment is the screening of potentially affected relatives for abnormalities of serum copper and ceruloplasmin; if any relative is found to have the disease, penicillamine should be given indefinitely to prevent the emergence of neurologic symptoms. A full explanation of the dangers of ceasing the medication must be given, and compliance may have to be monitored.

**Hereditary Deficiency of Ceruloplasmin** This is a rare illness, quite similar to Wilson disease, occurring in patients with a recessively inherited deficiency of ceruloplasmin; it is not simply a heterozygous form of Wilson disease (the mutation involves a different gene). Cirrhosis and Kayser-Fleischer rings are not features of the disease, but diabetes is common and extrapyramidal signs may or may not arise. Rather than copper, iron is deposited in the brain and liver (see discussion by Logan). Those few cases that have been well studied, mainly Japanese, show mainly an ataxic disorder (Miyajima et al).

Also noted here is a rare and poorly characterized progressive myelopathy that closely simulates subacute combined degeneration of B12 deficiency; it recently has been associated with low serum copper levels (page 1078).

**Hallervorden-Spatz Disease** This disease is also known as pigmented degeneration of the globus pallidus, substantia nigra, and red nucleus. It is inherited as an autosomal recessive trait and is due, in all classic cases, to a defect in the gene encoding pantothenate kinase 2 (PANK2) usually in the form of a missense mutation. The onset of symptoms is in late childhood or early adoles-
ence, and it progresses slowly over a period of 10 or more years. The early signs are highly variable but are predominantly motor, both corticospinal (spasticity, hyperreflexia, Babinski signs) and extrapyramidal (rigidity, dystonia, and choreoathetosis). General deterioration of intellect is conjoined. In individual cases, ataxia and myoclonus have appeared at some phase of the illness. The spasticity and rigidity are most prominent in the legs, but in some instances they begin in the bulbar muscles, interfering with speech and swallowing, as happens in Wilson disease. We have observed patients who, over a period of years, exhibited only dystonia of the tongue, blepharospasm, or arching of the back. The relationship of this restricted form to the complete syndrome remains unsettled. Eventually, the patient becomes almost completely inarticulate and unable to walk or use his or her arms. Optic atrophy has been mentioned in a few reports, but we have not observed it. Hayflick and colleagues have found that only one-third of patients with atypical forms of the disease have mutations of the PANK2 gene, and these are of a different type than in the classic disease. Moreover, variant cases tended not to show the characteristic changes on MRI described below.

Reduced levels of PANK2 corroborate the diagnosis, but this test is available only in research laboratories with an interest in the disease. The characteristic deposits of iron in the basal ganglia have not been associated with a demonstrable abnormality of serum iron or of iron metabolism. It has, however, been reported that there is a high uptake of radioactive iron in the region of the basal ganglia following intravenous injection of labeled ferrous citrate (Vakil et al, Szanto and Gallyas). CT scanning reveals hypodense zones in the lenticular nuclei, resembling those of hepatolenticular degeneration, sublute oxidase deficiency, glutaric acidemia, and Leigh disease, although high-density lesions have been described in one autopsy-proven case of this disease (Tennison et al).

The MRI findings are striking (Fig. 37-8). In T2-weighted images, the pallidum appears intensely black, with a small white area in its medial part ("eye of the tiger" sign; see also Savoiardo et al).

The neuropathology proves to be the most distinctive attribute of the disease. There is an intense brown pigmentation of the globus pallidus, substantia nigra (especially the anteromedial parts), and red nucleus. Granules and larger amorphous deposits of iron mixed with calcium stud the walls of small blood vessels or lie free in the tissue. A loss of neurons and medullated fibers occurs in the most affected regions. Another unique feature is the presence of swollen axon fragments, which resemble those of neuroaxonal dystrophy; for this reason, some neuropathologists regard Hallervorden-Spatz disease as a juvenile form of neuroaxonal dystrophy. Iron deposits are less conspicuous in the latter disease, leaving this interpretation in doubt. The significance of iron deposition is difficult to judge. To some extent, there is an increase of iron in the basal ganglia in other degenerative diseases. In Parkinson disease and striatonigral degeneration, for example, the deposition of iron is two to three times normal, presumably the result of degeneration of those tissues that are known to be rich in iron.

No treatment is known to be effective. Some of our patients responded temporarily to L-dopa, but the effect was slight. The use of chelating agents to reduce iron storage has not helped.

**Differential Diagnosis of Wilson and Hallervorden-Spatz Diseases** Disorders that must be differentiated from Wilson and Hallervorden-Spatz diseases are tardive dyskinesia, restricted forms of dystonia, adult and juvenile Parkinson disease and the related Segawa type of L-dopa–responsive dystonia, early-onset rigid form of Huntington chorea, status dysmyelinitus, Fahr disease (see below), Lafora-body disease, Leigh subacute necrotizing encephalomyelopathy, multiple sclerosis, dentatorubropallidolysian degeneration, ceroid lipofuscinosis, polyglucosan disease, and other rare, presumably biochemical disorders of unknown type. Several probable cases evoking these different diagnoses have come to our attention; in each there were some components of the extrapyramidal picture of Wilson disease but without evidence of liver involvement or copper abnormality. Difficult to categorize are diseases such as the one reported by Willvonseder and colleagues and by Tagawa and coworkers—in which a mild dementia, spastic dystrophia, paresis of vertical eye movements, gait disturbance, and splenomegaly came on during early adult life. Here, abnormalities of copper metabolism were found (slightly decreased serum ceruloplasmin, copper turnover values in the range of those in heterozygous carriers of Wilson disease), but there was no increase in urinary copper excretion. It is not known if they carry the Wilson gene. The authors have seen two such patients. One in her fifties had the subacute onset of parkinsonism with severe dystrophia, Wilsonian facies, mild ataxia, and exaggerated facial and limb reflexes. There were no Kayser-Fleischer rings. There were symmetrical signal changes in the MRI in the pallidum and dentate nucleus and diffusely through the white matter. She stabilized without treatment.

In families known to have Huntington chorea, children and some adults may be afflicted with a predominantly rigid-parkinsonian form (Westphal variant). About 5 percent of all cases of Huntington chorea are of this “juvenile type.” Rather than a movement disorder, this condition is marked by a slow decay in intellect, slurred speech, rigidity of the limbs, short-stepped gait, and flexion hypertonia of the limbs and trunk. Nevertheless, choreoathetosis does eventually appear in most cases. Ocular movements are full except for upward gaze. The disease is inexorably progressive, and eventually the patient becomes mute and rigidly immobile, with mouth agape, limbs flexed, and hands fist in fixed, dystonic postures. Progressive supranuclear palsy may for a considerable period of time lack the characteristic limitation of vertical gaze, or it may be minimal. The main features are then axial rigidity, extension.
dystonia of the neck, and some rigidity and dystonia of the limbs. This differentiation has presented problems in diagnosis in a few of our patients whose illness began in their late forties or fifties. See Chap. 39 for discussion of the neuropathology and treatment of these two diseases.

Juvenile paralysis agitans was described by Ramsay Hunt in 1917. Judging by the descriptions, the resemblance to adult Parkinson disease is close. The course was slowly progressive. Postmortem examination showed a shrinkage of the lenticular nuclei and a loss of large cells in the pallidum, but in an anatomic specimen from van Bogaert’s laboratory (the age of onset was 7 years), cell loss was noted in the substantia nigra and pallidum. This type of case is being increasingly recognized and is probably related to the early-onset type of parkinsonism-dystonia that is responsive to L-dopa or to one of the emerging group of mutations of the Parkin gene, as discussed in Chap. 39.

In isolated late-life cases of Lafora-body disease (discussed earlier in this chapter), there may be rigidity, akinesia, and tremor; but usually myoclonus, seizures, and dementia dominate the picture. Rarely, the mitochondrial disorder of Leigh disease (described later in the chapter) gives rise to a slowly evolving extrapyramidal rigidity in late childhood or adolescence, with bilateral cavitation of the putamen in CT scans.

The differential diagnosis of the aforementioned diseases continues to present certain difficulties. The recognition of Hallervorden-Spatz disease was for many years a clinical problem bereft of a satisfactory laboratory test, but this has been partially simplified by MRI. The similarities between the diseases included under the rubric of the Parkinson syndrome are in general smaller than the differences. Wilson disease, for example, shares certain signs with Parkinson disease, yet each possesses distinctive features of each. The special qualities of the facial expression in Wilson disease—as well as the dysthria, severe ataxic tremor, rigidity, and dystonia—are not likely to be confused with Parkinson disease. Furthermore, in several of the diseases in this category, there may be myoclonus and extrapyramidal signs such as choreoathetosis, dystonia, and so on, which are essential parts of the next category of syndromes. Therefore one must not insist that each disease conform strictly to a unique clinical syndrome.

Syndromes of Dystonia and Generalized Chorea and Athetosis

As indicated in Chap. 4, the differences between dystonia and choreoathetosis are not fundamental. If one examines many patients with these involuntary movements, every gradation between the two is seen, and not infrequently, the quicker, unpatterned involuntary movements of mild ballismus are added. Even tremor and myoclonus may complicate the composite movement disorder. With reference to muscular tone in patients with athetosis and dystonia, there are unpredictable associations of hypertonia and hypotonia.

A number of inherited metabolic diseases, all of them rare, express themselves by this syndrome of chorea, athetosis, and dystonia.

The Lesch-Nyhan Syndrome and Hyperuricemia This rare metabolic disease is inherited as an X-linked recessive trait. Although it carries the names of Lesch and Nyhan (1964), the occurrence of uricemia in association with spasticity and choreoathetosis in early childhood had been described earlier by Catel and Schmidt.

Essentially it is a hereditary choreoathetosis with self-mutilation and hyperuricemia. The affected children appear normal at birth and usually develop on schedule up to 3 to 6 months of age. Maturational delay then sets in, initially with hypotonia that later gives way to hypertonia. Also, the patient’s behavior becomes abnormal, with aggressiveness and compulsive actions. The uncontrollable self-mutilation, mainly of the lips, occurs early (during the second and third year), and spasticity, choreoathetosis, and tremor come later. Most of the children learn to walk. Speech is delayed, and once attained, it is dysarthric and remains so throughout life. Mental retardation is moderately severe. In patients more than 10 years of age, gouty tophi appear on the ears, and there is increasing risk from gouty nephropathy. The serum levels of uric acid are in the range of 7 to 10 mg/dL.

A deficiency of the enzyme hypoxanthine-guanine-phosphoribosyl transferase (HPRT) has been found in all typical cases of this disease. The HPRT gene lies on the X chromosome (Xq 26-q 27), and accurate diagnosis of affected males and carriers can be made by DNA analysis. As a result of this deficiency, hypoxanthine is either excreted or catabolized to xanthine and uric acid. The details of the biochemical abnormality responsible for CNS dysfunction are unclear.

In the differential diagnosis, one must consider nonspecific mental retardation or autism with hand biting and other self-mutilations, athetosis from birth trauma, and encephalopathies with chronic renal disease. Hyperuricemia has also been reported in a family with spinocerebellar ataxia and deafness and in another with autism and mental retardation, neither of them with the enzymatic defect of Lesch-Nyhan disease. As mentioned earlier, there are several other disorders of purine and pyrimidine metabolism, some of them with hyperuricemia, that present with a neurologic syndrome like that of Lesch-Nyhan.

Treatment This is with the xanthine oxidase inhibitor allopurinol, which blocks the last steps of uric acid synthesis, reduces the uric acid in Lesch-Nyhan disease, and prevents the uricosuric nephropathy, but it seems to have no effect on CNS symptoms. Guanosine 5-monophosphate and inosine 5-monophosphate, both of which are deficient in Lesch-Nyhan disease, have been replaced without benefit to the patient. Transitory success has also been achieved by the administration of 5-hydroxytryptophan in combination with L-dopa. Fluphenazine (Prolixin) is reported to have suppressed the self-mutilation after haloperidol (Haldol) had failed to do so. Behavior modification programs may be of some value.

Calcification of Vessels in Basal Ganglia and Cerebellum (Hypoparathyroidism and Fahr Syndrome) Ferruginization and calcification of vessels in the basal ganglia occur to a slight degree in many elderly persons (and in other mammals) who are otherwise normal. The widespread use of CT scans and MRI has brought the condition to light with increasing frequency (Fig. 37-9). Usually it may be dismissed as an aging phenomenon of no clinical significance. When it occurs early in life and is of such degree as to be visible in plain films of the skull, it must always be regarded as abnormal. An adult case of this type was described by Fahr, so that his name is sometimes attached to this disorder, but it was known long before his publication appeared, and his account added little to our knowledge of the condition.

Many authors have called attention to a form of calcification of the basal ganglia and cerebellum in which choreoathetosis and rigidity are prominent. The clinical state may also take the form of a parkinsonian syndrome or bilateral athetosis. In two of our pa-
patients there was a unilateral choreoathetosis, which was replaced gradually by a parkinsonian syndrome, and in another of our sporadic cases, the initial abnormality was a unilateral dystonia, responsive to L-dopa. Some patients have been mentally retarded, others intellectually intact. We have observed a familial form of basal ganglionic-cerebellar calcification inherited as an autosomal recessive trait. Its onset was in adolescence and early adult life, and it presented clinically as a complex syndrome of choreoathetosis, tremor, ataxia, and dementia. The serum calcium levels in the aforementioned types of cases are usually normal, and there is no explanation of the calcification. This was also true of our cases. In a family described by Martinelli and colleagues, there was autosomal dominant inheritance and abnormal vitamin D metabolism.

In hypoparathyroidism (idiopathic or acquired) and pseudo-hypoparathyroidism (a rare familial disease characterized by the symptoms and signs of hypoparathyroidism in association with distinctive skeletal and developmental abnormalities), the diminution in ionized serum calcium induces not only tetany and seizures but sometimes choreoathetosis as well. This last symptom is presumably due to calcification of the basal ganglia, which occurs in about one-half of the patients. Also, in some instances there are signs of a cerebellar lesion.

Sly and colleagues have described the familial occurrence (21 cases in 12 families) of calcification in the caudate and lenticular nuclei, thalami, and frontal lobe white matter in association with osteopetrosis (“marble bones”) and renal tubular acidosis. Clinically there were multiple cranial nerve palsies—including optic atrophy as well as psychomotor delay and learning disabilities—but no extrapyramidal signs. The cranial nerve palsies, which are due to bony encroachment in neural foramina, were much less severe than in the lethal form of osteopetrosis. The pattern of inheritance of this disease is autosomal recessive, and the basic abnormality was found to be a deficiency in carbonic anhydrase II in red blood corpuscles and probably in kidney and brain.

**Other Metabolic Disorders Associated with Choreoathetosis and Dystonia**  
Exceptionally, ceroid-lipofuscinosis of the Kufs type, GM1 gangliosidosis, late-onset metachromatic leukodystrophy, Niemann-Pick disease (type C), Hallervorden-Spatz disease, and Wilson disease may present with a syndrome in which dystonia or athetosis is an important component. Usually, there are other elements in the clinical picture as well, so that the correct diagnosis is seldom in doubt for long. Dal Canto and colleagues have described a variant of neuronal ceroid-lipofuscinosis in which a boy and girl of unrelated non-Jewish parents developed severe choreoathetosis and dystonia at 6 to 7 years of age. Intellectual deterioration, gait abnormality, and seizures were added clinical features. Cerebral biopsy showed intraneuronal inclusions consisting of curvilinear bodies. These observations support the notion of nosologic heterogeneity among the nonglycolipid neuronal storage disorders.

**Glutaric acidemia** (type I) is another rare metabolic disorder, in which progressive choreoathetosis and dystonia are combined with an intermittent acidemia. In some cases, ataxia of movement and a variable degree of mental retardation are also present. Glutaric acid is present in the urine, as are its metabolites 3-OH glutarate and glutamate. The basic defect is in glutaryl CoA dehydrogenase, which has been found in leukocytes, hepatocytes, and fibroblasts. Neuropathologically, there is loss of neurons in the caudate, putamen, and pallidum, with gliosis. A spongy change is said to affect the white matter.

Infants with glutaric acidemia are often subject to sudden episodes of acidosis, coma, and flaccidity. There are signal changes on MRI, corresponding to the acute necrosis of nerve cells in the basal ganglia. These crises can be prevented and the infants can develop normally if the diagnosis is made before the development of neurologic signs, for example, in the sibling of an older affected child, and treatment is undertaken with a diet low in protein, particularly in tryptophan and lysine (Cho et al).

It should be pointed out that acquired extrapyramidal disorders are much more common than inherited ones. A prototype of athetosis is known to follow hypoxic encephalopathy of birth, leading to *état marbré*; of the basal ganglia. This is the basis of the double athetosis syndrome that usually becomes manifest only after the first year of life and persists thereafter (page 878). The Rh and ABO blood incompatibilities that induce erythroblastosis fetalis and *kernicterus* are another cause of a bilateral athetosis at about the same period of life, but this syndrome is distinguished by intense and prolonged neonatal jaundice and the added features of deafness and paralysis of upward gaze (page 878). The same is true of the Crigler-Najjar form of hereditary hyperbilirubinemias, in which kernicterus (with ataxia or athetosis) may rarely appear as late as childhood or adolescence, the defect being one of glucuronic-bilirubin conjugation. Later in life, the antiphospholipid antibody syndrome may induce chorea as a presenting feature (see page 735).

Finally, a number of other rare diseases, which can only be classified as heredofamilial degenerations, must also figure in the differential diagnosis of choreoathetotic or dystonic syndromes and are covered in Chap. 39. Torsion dystonia is the best-known example. Another is the familial dystonia with certain features of Parkinson disease which is highly responsive to L-dopa (Segawa disease). The distinctive chorea-atachonotic syndrome is described on page 913. A nonprogressive familial choreoathetosis with onset in early childhood has been reported by Pincus and Chutorian; here, cerebellar signs were usually conjoined but the

---

Figure 37-9. Idiopathic basal ganglionic and cerebellar calcification discovered 5 years after the onset of a slowly progressive rigid Parkinson syndrome in a 54-year-old woman.
intellect was spared. This syndrome is probably inherited as an autosomal recessive trait. A paroxysmal and sometimes kinesogenic form of familial choreoathetosis was recognized by Mount and Reback in 1940 and subsequently elaborated upon by Lance (page 68). One wonders in retrospect if some of these patients were dopamine-responsive. We have observed attacks of this kind in children with “cerebral palsy” as a manifestation of phenytoin (or carbamazepine) toxicity; lowering the dose of the drug terminated the attacks. Sethi and coworkers have described an adult with dementia and choreoathetosis, simulating Huntington chorea, in whom episodic nausea, vomiting, and lethargy during childhood were due to propionic aciduria. The movement disorder did not appear until the patient was 28 years old. In others, the chorea begins in infancy and persists despite all attempts at treatment. The authors have grouped this disease with the other inherited choreas (Huntington disease, neuroacanthocytosis, familial calcification of basal ganglia, Hallervorden-Spatz disease, acanthocytic chorea, dentatorubrothalamic atrophy).

Most of the above-mentioned diseases are presently classified as degenerative and are discussed in Chap. 39.

SYNDROMES OF BILATERAL HEMIPLEGIA, CEREBRAL BLINDNESS, AND OTHER MANIFESTATIONS OF DECREBERATION (THE LEUKODYSTROPHIES)

Categorized here are the features that characterize disorders of the cerebral white matter by which most of the familial leukodystrophies are expressed. Of the several varieties of late-onset leukodystrophy, some are of unquestionable metabolic origin and others are of uncertain status. The terms metachromatic, sudanophilic, orthochromic, etc., refer to the distinctive products of myelin degeneration and staining characteristics (or lack thereof) of the white matter in the individual leukodystrophies. As emphasized earlier, all differ from the cerebral gray matter diseases (poliodystrophies), which have a different mode of presentation—seizures, myoclonus, chorea, choreoathetosis, and tremor being prominent. Instead, recognition of the entire group of leukodystrophies is based on symptoms and signs attributable to the interruption of tracts (corticospinal, corticobulbar, cerebellar peduncular, sensory, medial longitudinal fasciculi) and visual pathways (optic nerve, optic tract, geniculocalcarine) and the infrequency or absence of seizures, myoclonus, and spike-and-wave abnormalities in the EEG. However, this distinction is not infallible, particularly in the later stages of the disease.

The syndrome of progressive spasticity and rigidity with spastic dysthria and pseudobulbar palsy poses another difficult diagnostic problem. One’s first impulse is to assume the presence of a corticospinal disorder, especially if tendon reflexes are brisk, but frequently the plantar reflexes are flexor and the facial reflexes are not enhanced. In addition, unusual postures and a more plastic type of rigidity may occur, consistent with an extrapyramidal condition. Furthermore, the combination of reduced or absent tendon reflexes and Babinski signs, signifying a combination of corticospinal and peripheral nerve lesions, is highly characteristic of metachromatic leukoencephalopathy, adrenomyeloneuropathy, or subacute combined degeneration of the spinal cord (vitamin B12 deficiency). Such combinations, with mental backwardness and dementia, characterize the mild and late forms of metachromatic leukodystrophy.

The leukodystrophies that become apparent only in later life pose another problem—the clinical and radiologic differentiation from cerebral forms of multiple sclerosis. In cases of early onset, in which myelin has yet to be normally formed, the metabolic disturbance may result in hypomyelination (e.g., Pelizaeus-Merzbacher disease); by contrast, the process in adolescent or adult-onset cases is one of destruction of myelin already formed. In identifying the metabolic diseases of myelin, one is helped by the relatively symmetrical and steady progression of the clinical signs; the early onset of cognitive impairment (which is uncharacteristic of multiple sclerosis); and the symmetrical and massive degeneration of the cerebral white matter (in distinction to the asymmetrical and often multiple lesions of demyelinating disease). At various times in life, particularly in young individuals, the rare vascular disorder called CADASIL enters into the differential diagnosis (see Chap. 34); late in life, distinguishing a metabolic disorder of myelin from the subcortical multiple infarctions ofBinswanger disease and from the ubiquitous rarefaction of the periventricular regions of the cerebrum may be a problem. Differentiation from cerebral gliomatosis, brain lymphoma, and progressive multifocal leukoencephalopathy, all affecting deep cerebral or white matter structures, offers less difficulty.

Adrenoleukodystrophy (ALD; Sudanophilic Leukodystrophy with Bronzing of Skin and Adrenal Atrophy)

This combination of leukodystrophy and Addison disease, originally included under the rubric of Schilder disease, is now set apart as an independent metabolic encephalopathy. It is transmitted as an X-linked recessive trait with an incidence of 1 in 20,000 male births. The fundamental defect is an impairment in peroxisomal oxidation of very-long-chain fatty acids (VLCFAs), leading to their accumulation in the brain and adrenal glands (see the publications of H. Moser and of Igarashi and associates). The deficient membrane protein, encoded by a gene that maps to chromosome X28, is a peroxisomal membrane transporter (ABCD1). The gene is located close to the gene for color vision. In the typical X-linked ALD, there is an inability to metabolize VLCFAs, but it came as a surprise that the disease was not caused by an enzyme deficiency. The modern classification of the disease categorizes it as a disorder of peroxisomes, subcellular organelles containing numerous enzymes. This peroxisomal assignment connects adrenoleukodystrophy with Zellweger and Refsum disease.

The onset is usually between 4 and 8 years, sometimes later; in the most common form of this disorder, only males are affected with the entire syndrome (women carriers may display a special myelopathy discussed further on). The signs of either the adrenal insufficiency or the cerebral lesion may be the first to appear. In the case of Siemerling and Creuzfeldt, the first recorded example of this disorder, bronzing of the skin of the hands appeared at 4 years of age; quadripleasia, with dystarhria and dysphagia (i.e., pseudobulbar palsy), became evident at 7 years; a single seizure occurred at 8 years; and by 9 years, shortly before death, the patient was decerebrate and unresponsive. In personally observed cases, the first abnormalities appeared at 9 to 10 years and took the form of episodic vomiting, decline in scholastic performance, and change in personality, with silly, inappropriate giggling and crying. After a time, severe vomiting and even an episode of circulatory collapse occurred, following which the gait became unsteady and arms ataxic, with an action or intention tremor. Only then did the Addisonian increase of pigmentation of the oral mucosa and the
skin around nipples and over elbows, knees, and scrotum become evident. *Cortical blindness* followed in some instances. The late stages were marked by bilateral hemiplegia (at first asymmetrical), pseudobulbar paralysis, blindness, deafness, and impairment of all higher cerebral functions.

The severity of the disease varies. We are caring for two adult men in whom the cerebral symptoms have been mild, allowing for high-level cognitive achievement, albeit with peculiarities of personality, and with mild spastic gait, urinary difficulty, testicular insufficiency, and baldness. In each family there was a male sibling who died in childhood, ostensibly of adrenal insufficiency.

Griffin and coworkers have described a spinal-neuropathic form of the disease (adrenomyeloneuropathy, AMN). In their patients, evidence of adrenal insufficiency had been present since early childhood, but only in the third decade of life did a progressive spastic paraparesis and a relatively mild polyneuropathy develop. It should be noted that the spasticity is occasionally asymmetrical, and the gait may have an ataxic component. This neurologic picture, in mild form and without adrenal insufficiency, is also the manner in which the disease may present in female carriers of the gene abnormality (see below). Like adrenoleukodystrophy, AMN is typically inherited as an X-linked, male-specific trait. However, we have encountered a large family with adrenomyeloneuropathy in which males and females are both affected in a pattern that suggests dominant inheritance. The VLCFAs are modestly elevated in affected individuals, and there is no evidence of cerebral involvement.

Moser and colleagues, using clinical and biochemical criteria, have identified the following subtypes of ALD:

1. A progressive degeneration of cerebral white matter in young males, often with cortical blindness—the classic type, accounting for half of all cases (Fig. 37-10)
2. An intermediate form in juvenile or young adult males with cerebral and spinal involvement (5 percent of cases)
3. A progressive spinal cord tract degeneration in adult males (25 percent of cases)
4. A chronic mild, nonprogressive spastic paraparesis in heterozygous female carriers (10 percent of cases)
5. Familial instances of Addison disease without neurologic involvement in males (10 percent)
6. Possibly, in male infants, a form originating at birth (e.g., Zellweger disease)

Illustrating the variability in presentation among kindreds, Marsden and colleagues and, subsequently, Kobayashi and coworkers described a familial spinocerebellar syndrome, and Ohno and associates have reported a sporadic instance of adrenoleukodystrophy presenting as olivopontocerebellar atrophy. Moser found cerebral forms alone in 30 percent, adrenomyeloneuropathy alone in 20 percent, and combined childhood cerebral and myelopathic forms in the remaining half.

**Female Heterozygotes** Neurologic manifestations have been said to develop in up to 50 percent of female carriers, but in our experience with siblings of affected patients, the figure has been lower. The onset of a *spastic paraparesis* tends to occur later in life, usually in the third or fourth decade, and progression tends to be slow, but an explosive onset has been reported (see Chap. 44). As already mentioned, multiple sclerosis is the main consideration in differential diagnosis, particularly since 20 percent of heterozygotes have white matter changes on cerebral MRI. Overt adrenal insufficiency is rare in female carriers, but scalp hair may be scant as a subtle manifestation of adrenal hypofunction.

Pathologically in classic instances, massive degeneration of the myelin occurs, often asymmetrically in various parts of the cerebrum, brainstem, optic nerves, and sometimes spinal cord (Fig. 37-10). Degradation products of myelin (sudanophil-positive) are visible in macrophages in recent lesions—namely, sudanophilic demyelination. There is extensive astrocytic gliosis. Axons are damaged, but to a lesser degree. The cortex of the adrenal glands is atrophic, and the cells and invading histiocytes contain an abnormal lipid material. The testes show marked interstitial fibrosis and atrophy of the seminiferous tubules. Electron microscopically, the macrophages of the brain and adrenals and the Leydig cells of the testes contain characteristic lamellar cytoplasmic inclusions.

**Laboratory Diagnosis** The specific laboratory marker of the disease is an excess of VLCFAs, in particular three measurements are of value: the absolute level of hexacosanoic acid (C26), the ratio of C26 to tetracosanoic acid (C26:C24), and of C26 to docosanoic acid (C26:C22) in plasma, erythrocytes, leukocytes, or cultured fibroblasts as detailed by A. B. Moser and colleagues. This reflects the basic biochemical fault in this disease, namely defective fatty acid oxidation within the peroxisomes. If skin fibroblasts and plasma testing are both performed, 93 percent of female carriers will show the abnormal VLCFA. MRI of the brain is abnormal in the majority of patients with cerebral symptoms and in a proportion of others.

Other laboratory findings are low serum sodium and chloride levels and elevated potassium levels—reflecting the atrophy of the adrenal glands. The latter results in reduced excretion of corticosteroids, low serum cortisol levels, and lack of rise in 17-hydroxy-steroids after ACTH stimulation. The CSF protein may be elevated.

![Figure 37-10. Adrenal leukodystrophy in a 7-year-old male. Confluent areas of increased signal involving the frontal, occipital, and parietal white matter (thick arrow) and of the anterior and posterior portions of the corpus callosum (long-stemmed arrows). Treatment  Adrenal replacement therapy prolongs life and occasionally effects a partial neurologic remission. A diet enriched with monounsaturated fatty acids and devoid of long-chain fatty acids has been said to slow the progress of the disease when administered before the age of 6. Bone marrow transplantation, to date performed in over 50 children, has been the only treatment shown to stabilize the disease and reverse some of the MRI changes. The reviews by van Geel and colleagues, and the ones by Moser, the leading worker in the field, summarizing diagnosis and treatment, are recommended.

Juvenile and Adult Metachromatic Leukodystrophy (MLD)  This form of leukodystrophy has already been described in relation to the inherited metabolic disorders of late infancy and early childhood in an earlier section. It is mentioned here again to emphasize the point that the disease may have its onset at almost any age. Juvenile forms may begin between 4 and 12 years and adult forms between the midteens and the seventh decade. The mutations giving rise to these various forms are described in the earlier section on MLD. Some of the sporadic cases reported in the adult have probably been examples of cerebral multiple sclerosis, but we have seen, as have others, cases of MLD appearing as late as middle adult life. In almost all cases, the clinical picture, like those Turpin and Baumann, was one of slowly evolving intellectual decline or behavioral abnormality, followed by spastic weakness, hypertonia, Babinski signs, and stiff, short-stepped gait, with or without a polyneuropathy. Without manifest neurologic signs, misdiagnosis of psychiatric disease is common. As the disease progresses over a period of 3 to 5 years there may be a loss of vision and speech, then of hearing, and finally a state of virtual decerebration.

In some of these cases it is impossible to distinguish the white matter disease from that of Pelizaeus-Merzbacher and of Cockayne, described in the preceding section.

Orthochromatic Leukodystrophy  This refers to a heterogeneous group of disorders, also called nonmetachromatic leukodystrophy, in which no enzyme defect or special staining characteristic of degenerated white matter has been identified. Furthermore, most of them have been sporadic, obscuring the nosology of the process. One type is associated with cerebellar ataxia and dementia; other adult cases have been described in which epilepsy was associated with a frontal lobe type of dementia. A surprising feature, such as in the cases of Letournel and colleagues, has been normal MRI, even with the more sensitive FLAIR sequences.

Cerebrotendinous Xanthomatosis  This rare disease is probably transmitted by an autosomal recessive gene. It usually begins in late childhood, with cataracts and xanthomas of tendon sheaths and lungs. As it progresses, difficulty in learning, impairment of retentive memory, and deficits in attention and visuospatial perception (the earliest neurologic manifestations) give way to dementia, ataxic or ataxic-spastic gait, dysarthria and dysphagia, and polyneuropathy. In the late stages (after 5 to 15 years), the patient becomes bedfast and helpless; death occurs at 20 to 30 years of age. In other cases the clinical course is much more benign. Neuropathologic examination shows masses of crystalline cholesterol in the brainstem and cerebellum and sometimes in the spinal cord, with symmetrical destruction of myelin in the involved areas. The lesions are visible by CT scanning and MRI.

The basic defect is in the synthesis of primary bile acids, leading to an increased hepatic production of cholesterol and cholesteryl, which accumulate in brain and tendons. The serum cholesterol levels are normal in most cases but may be as high as 450 mg/dL in others. The tendon xanthomas contain cholesterol, of which 4 to 9 percent is cholesteryl (dihydrocholesterol) according to the studies of Moser. Cholesteryl levels in the serum and red cells are increased. The same elevated levels are found in heterozygotes.

Treatment  In response to long-term treatment with chenodeoxycholic acid, 750 mg daily, the corticospinal and cerebellar signs and dementia receded in 10 of 17 patients treated and followed by Berginer and coworkers. This drug corrects the defective synthesis of bile acids and restores the low level of chenodeoxycholic acid. Ideally treatment should begin before the neurologic symptoms appear (Meiner et al).

STROKES IN ASSOCIATION WITH INHERITED METABOLIC DISEASES

In Chap. 34 it was remarked that strokes occur from time to time in children and young adults, often due to inherited disorders of the clotting system typified by protein C deficiency, but also due to a number of other metabolic derangements including the mitochondrial disorder, MELAS. Among the many causes, three metabolic diseases must always be considered in the diagnosis of such cases: homocystinuria, Fabry disease, and sulfite oxidase deficiency. Other less common ones are Tangier disease and familial hypercholesterolemia. Stroke in young persons is also a central feature of the mitochondrial disorder MELAS, discussed further on in this chapter, and of the genetically determined microvasculopathy CADASIL (page 707).

Homocystinuria  This aminoaciduria is inherited as an autosomal recessive trait and simulates Marfan disease. Tall, slender habitus; great length of limbs, sometimes scoliosis and arachnodactyly (long, spidery fingers and toes); thin and rather weak muscles; knock-knees; highly arched feet; and kyphosis are the typical skeletal features. Sparse, blond, brittle hair; malar flush; and livedo reticularis are common dermal manifestations, and a dislocation of one or both lenses (usually downward) may occur, imparting a tremulous appearance to the irides (iridodendrosis). The only neurologic abnormality is mental retardation, usually of mild degree, which sets this syndrome apart from Marfan disease, in which intellect is unimpaired.

Blood vessel changes—thickening and fibrosis of the coro-

nary, cerebral, and renal arteries—tend to appear later in the illness. An abnormality of platelets favoring clot formation and thrombosis of cerebral arteries has been observed. Some patients have died of coronary occlusions during adolescence, and a myocardial lesion may be the source of emboli to cerebral arteries.

Homocystine is elevated in the blood, CSF, and urine. This is due to an inherited cystathionine synthase deficiency that results in an inadequacy of cystathionine formation, a substance essential to many tissues including the brain. This may be the explanation of the mental retardation. Plasma methionine levels are also elevated. The infarcts in the brain are clearly related to thrombotic and embolic arterial occlusions. The administration of a low-methionine diet and large doses (50 to 500 mg) of pyridoxine (a cystathionine synthase coenzyme) reduces the excretion of homocystine. If vascular lesions have occurred, anticoagulants probably prevent further occlusions.
Homocystinuria may also be an expression of 5,10-methyltetrahydrofolate reductase deficiency. Again, the clinical manifestations consist of multiple cerebrovascular lesions, dementia, epilepsy, and polyneuropathy. The last is believed to be due to a coincidental folic acid deficiency, but in some cases it may have been caused by chronic phenytoin administration (Nishimura et al).

Much milder elevations of serum homocystine have recently been recognized as contributing to the risk of coronary disease and stroke in otherwise normal individuals.

**Fabry Disease (Anderson-Fabry Disease, Hereditary Dystopic Lipidosis)** This disease, also known as angiokeratoma corporis diffusum, is inherited as an X-linked recessive trait. It occurs in complete form in males and in incomplete form in female carriers. The primary deficit is in the enzyme α-galactosidase A, the result of which is the accumulation of ceramide trihexoside in endothelial, perithelial, and smooth muscle cells of blood vessels as well as in renal tubular and glomerular cells and other visera and in nerve cells in many parts of the nervous system (hypothalamic and amygdaloid nuclei, substantia nigra, reticular and other nuclei of the brainstem, anterior and intermedialateral horns of the spinal cord, sympathetic and dorsal root ganglia).

The disease becomes manifest clinically in childhood or adolescence, with intermittent lancinating pains and dysesthesias of the extremities. A notable feature of these pains is their evocation by fever, hot weather, and vigorous exercise. Usually there is no sensory loss, but autonomic disturbances have been recorded in a series of our cases. Many years later there is a diffuse vascular involvement that leads to hypertension, renal damage, cardiomegaly, and myocardial ischemia. Thrombotic infarctions occur in the brain during early adult years. Occasional cases are discovered in adulthood with confluent cerebral white matter changes on MRI and progressive problems such as dysarthria.

The characteristic angiokeratomas tend to be most prominent periumbilically and resemble small angiomas that obliterate slightly with pressure. Desnick and colleagues have reviewed the neurologic, neuropathologic, and biochemical findings in this disease, and Cable, Kolodny, and Adams have written informatively on the autonomic aspects.

**Treatment** Enzyme replacement, given by infusion, is now available. The two main trials of this treatment, summarized in an editorial by Pastores and Thadhani, were each conducted quite differently. Both showed an improvement in kidney and other organ function but only one demonstrated a reduction in neuropathic pain, and neither studied the risk of stroke. Like enzyme replacement therapy for Gaucher disease, prolonged treatment is expensive; but some evidence from the trials cited above indicates that certain aspects of the disease are reversible.

The painful neuropathic features that have brought several cases to our attention are discussed with the polyneuropathies, on page 1159.

**Sulfite Oxidase Deficiency** This disorder was discussed briefly with the neonatal metabolic disorders (page 804). The occurrence of stroke as a complication of this disorder was placed on record by our colleagues Shih et al. A child 4.5 years of age, whose development had been retarded since birth (seizures and opisthotonos had been present), became hemiplegic. Another unrelated child, supposedly normal until 2 years of age, entered the hospital with fever, confusion, generalized seizures, right hemiplegia, and aphasia (infantile hemiplegia); subluxation of the lenses (upward) was discovered later. There was an increased level of sulfite and thiosulfite and an abnormal amino acid, S-sulfocysteine, in the blood. One child appeared to respond to a low sulfur–amino acid diet.

**CHANGES IN BEHAVIOR AND INTELLECT AS MANIFESTATIONS OF INHERITED METABOLIC DISEASE**

Although rare among the vast numbers of maladjusted, sociopathic, and psychotic adolescents in our society, certain metabolic diseases may be the cause of serious disturbances of mental life and behavior. The diagnosis and management of these metabolic diseases are so unusual that some special remarks are appropriate.

All the metabolic diseases of late childhood and adolescence may share to some degree the property of deranging behavior, thinking, feeling, and emotional reactions. Usually, they present later in adolescence and adult life and evolve more slowly than childhood forms. The most obvious and easily detectable of these derangements are in the cognitive sphere, i.e., reduction in the capacity to learn and remember, to calculate, to solve problems, and to exercise verbal skills. Impulsivity, loss of self-control, and antisocial behavior are the most troubling behavioral abnormalities.

Certain forms of these impairments are attributable to integrated systems of modules of cerebral neurons and are recognized as special neurologic deficits, such as disinhibition or muting of behavior and affect, the amnesic state, aphasia, dyscalculia, and visual-perceptual disorientation. Each of these phenomena has its own cerebral anatomy, as pointed out in Chap. 22, and the state known as dementia comprises various degrees and combinations of these abnormalities.

Intellectual functions are little developed in early childhood; it is therefore difficult to judge the normal qualities of the mind for this age group. Slowness in learning and in acquiring language functions become manifest in school, and may then be interpreted loosely as mental retardation. Up until school age, these intellectual functions have not developed sufficiently to allow recognition of their regressive course. Only in late childhood do mental retardation and dementia become clearly distinguishable and measurable by standardized tests. Far less tangible are subtle changes in personality and behavior that must always be judged against the standards of the cultural group of which the patient is a member.

The principle that most neuropsychiatrists follow in selecting from the large mass of maladjusted adolescents those with a metabolic brain disease is that such a condition will sooner or later cause a regression in cognitive and intellectual functions. Schizophrenia and manic-depressive psychosis and the sociopathies and character disorders do so little or not at all. This is not to say that personality changes and emotional disturbances do not occur in the metabolic encephalopathies; they certainly do. However, their recognition depends more on the demonstration of failing memory, impaired thinking, inability to learn, and loss of verbal and arithmetic abilities, many of which are measuredquantitatively by intelligence tests. The appearance of pyramidal signs, aphasia, apraxia, ataxia, or areflexia always sets them apart.

If one reviews all the diseases described in this chapter and selects those that may demonstrate regression in cognitive function in association with personality change and alteration of behavior—diseases that may for a time be unaccompanied by other neurologic abnormalities—the following merit special consideration:
1. Wilson disease
2. Hallervorden-Spatz pigmentary degeneration
3. Lafora-body myoclonic epilepsy
4. Late-onset neuronal ceroid-lipofuscinosis (Kufs form)
5. Juvenile and adult Gaucher disease (type III)
6. Some of the mucopolysaccharidoses
7. Adrenoleukodystrophy
8. Metachromatic leukodystrophy
9. Adult GM$_2$ gangliosidosis
10. Mucolipidosis I (type I sialidosis)
11. Non-Wilsonian copper disorder (hereditary ceruloplasmin deficiency)

In each of these diseases, dementia and personality disorder may gradually develop and persist for many months, even a year or two, before other neurologic signs appear. One must look carefully for the earliest signs of movement disorders and other neuroligic abnormalities, which greatly clarify the diagnostic problem. A safe rule is to assume that if there are mental and personality changes in each of the above diseases, other subtle neurologic disorders coexist. The common use of neuroleptic drugs, causing tardive dyskinesia, is the major obstacle to applying this rule. The differential diagnosis includes a number of developmental disorders, mainly autism and Rett syndrome.

**ADULT FORMS OF INHERITED METABOLIC DISEASES**

The increasing range and precision of biochemical and cytologic tests has brought to light a number of inherited metabolic diseases that sometimes have their onset in adult life. Such disorders, while uncommon, nevertheless are important because they must be considered in the differential diagnosis of degenerative diseases and cerebral atrophies, for which explanations are beginning to be found. Also to be considered in the differential diagnosis is an array of mitochondrial disorders, to be discussed further on in this chapter.

In the last decade or two, the authors have personally observed or have otherwise come to know of examples of the following metabolic diseases, the onset of which was in late adolescence or adult life:

1. Metachromatic leukoencephalopathy
2. Adrenoleukodystrophy
3. Globoid body leukodystrophy (Krabbe disease)
4. Kufs form of neuronal ceroid lipofuscinosis
5. GM$_2$ gangliosidosis
6. Wilson disease
7. Leigh disease
8. Gaucher disease
9. Niemann-Pick disease
10. Mucopolysaccharide encephalopathy
11. Mucolipidosis type I
12. Polyneuropathies (Andrade disease, Fabry disease, porphyria, Refsum disease)
13. Mitochondrial diseases, particularly progressive external ophthalmoplegia and Leigh disease

In the encephalopathic forms of the metabolic and mitochondrial diseases, the diagnosis is usually made only after symptoms have been present for months or years, the disease having been mistaken for some other condition, particularly depression or a degenerative dementia. Even a manifest psychosis may have occurred in relation to some of these disorders, but such occurrences are admittedly rare. For example, one of our patients with metachromatic leukodystrophy, a 30-year-old man, began failing in college years and was later unsuccessful in holding a job because of carelessness and mistakes in his work and indifference to criticism, irritability, and stubbornness (clearly traceable to a mild dementia). Only when Babinski signs and loss of tendon reflexes in the legs were detected was the correct diagnosis entertained for the first time. By then he had been ill for nearly 10 years. Bosch and Hart described a patient with the onset of dementia at 62 years of age and drew attention to 27 other similar cases of adult-onset metachromatic leukoencephalopathy (see also the seven cases of Turpin and Baumann). Overt signs of neuropathy are usually lacking in these adult-onset cases, but EMG and sural nerve biopsy will disclose the characteristic abnormalities.

One of our adult patients with Wilson disease had been committed to a psychiatric hospital because of his paranoid tendencies and fighting with his family; the presence of a tremor and mild rigidity of the limbs had been attributed at first to phenothiazine drugs. In some of Griffin’s cases of adrenomyeloneuropathy, a spastic weakness of the legs and sensory ataxia progressing over several years were the main clinical manifestations; a spinocerebellar degeneration was suspected. One of our patients with Kufs lipid storage disease began to deteriorate mentally in early adult life and only much later showed an increasing rigidity, with atrophic posturing of limbs and difficulty in walking; he succumbed to his disease after more than a decade of symptoms. Another recent patient with Kufs disease presented at age 51 with vague visual difficulty, which was followed by spasticity of the legs, behavioral disinhibition, and dementia spanning 6 years. Josephs and colleagues describe two patients of five with adult-onset type C Niemann-Pick disease who had a psychosis beginning at ages 61 and 27, respectively.

We have observed cerebellar ataxia, polymyoelonus, and progressive blindness in adolescents and adults with a variant of GM$_2$ gangliosidosis; cherry-red macular spots provided the clue to diagnosis. Several such cases have been reported in the last decade, particularly among the Japanese (Miyatake et al). Notable also are nine cases of a spinocerebellar ataxia from four Ashkenazic Jewish families with dementia or psychosis of adult onset described by Wilner and colleagues. Also on our services have been two adult patients with progressive spinal muscular atrophy who proved to have this same GM$_3$ hexosaminidase deficiency; the process was clinically almost indistinguishable from a very slowly progressive lower motor neuron form of motor neuron disease (such as Kugelberg-Welander disease in adolescents), but they had no macular changes and displayed the additional features of ataxia and an intermittent and atypical psychosis.

Dementia, optic atrophy, mild cerebellar ataxia, and corticospinal signs have been features of several personally observed patients with Leigh disease who survived in a relatively helpless state for nearly 20 years. Kalimo and associates have reported a similar family. An asymmetrical corticospinal syndrome with areflexia had advanced so slowly in one of our cases of Krabbe disease that she became disabled only in her sixties.

Another of our patients, an adolescent with severe diffuse myoclonus and seizures and slight intellectual deterioration, was found after several years to have one of the rare variants of Gaucher disease. Another with dementia, rigidity, choreoathetosis, slight cerebellar ataxia, and Babinski signs had a variant of Niemann-
As with the metabolic disorders of the nervous system, the diseases included under this heading are so diverse and may involve so many parts of the nervous system that the clinical entities by which they are identified cannot be easily addressed in any one part of this book. In their overlapping relationships, however, these diseases are unlike the more discrete clinical entities caused by nuclear genetic mutations. Their diversity is evident not only in certain details of their clinical presentations but also in the age at which symptoms first become apparent, and—what is most intriguing—sometimes in the abrupt onset of their neurologic manifestations. Most of this variability is understandable from the principles of mitochondrial genetics outlined in the introductory section of this chapter. Of particular importance is the mosaicism of the mitochondria within cells and from cell to cell and the crucial role the organelles play in the oxidative energy metabolism that supports the function of cells in all organs. Fortunately for the clinician, the most important of these diseases are expressed in several recognizable core syndromes and in a few variants thereof. A number of acronyms formed from the initial letters of the main clinical features have been used to designate the major mitochondrial syndromes: MERRF, MELAS, PEO, NARP, etc., as summarized in Table 37-9. The addition of certain subtle dysmorphic features—including short stature; endocrinopathies, particularly diabetes; and a number of other systemic abnormalities such as lactic acidosis (discussed further on)—aids in diagnosis.

These diseases are the result of mutations in the mitochondrial

* Mitochondrial encephalomyopathy, lactic acidosis, and stroke. SOURCE: Adapted with permission from Grey et al.

Pick disease. For many years our colleagues had under observation a family with Gaucher disease, several members of which had developed seizures, generalized myoclonus, supranuclear gaze palsies, and cerebellar ataxia in early adult life (Winkelman et al). Rarely, Gaucher disease may be associated with an early and severe parkinsonian syndrome.

We have had the experience of finding laboratory evidence of adrenal insufficiency in young men with white matter lesions of the frontal lobes and other parts of the cerebrum; there was no bronzing of the skin, and earlier a diagnosis of multiple sclerosis had been made. Eldridge and coworkers have described a large kindred with widespread noninflammatory degeneration of the cerebral and cerebellar white matter; individual members were thought to have multiple sclerosis before a pattern of autosomal dominant inheritance became evident (possibly this represents CADASIL, page 707). Such cases are likely to be found in multiple sclerosis clinics. Adrenoleukodystrophy presenting in adult life as a spino cerebellar or olivopontocerebellar syndrome has already been mentioned.

These rare forms of inherited metabolic disease are notable for their chronicity and for the early prominence of a particular neurologic symptom or syndrome. Once the disease is established, however, there is nearly always evidence of involvement of multiple neuronal systems, reflected in a subtle or overt dementia, character disorder, or signs referable to corticospinal, cerebellar, extrapyramidal, visual, and peripheral nerve structures. This multiplicity of neuronal system involvement is much more a feature of inheritable metabolic disease than of degenerative disease, and the finding of such involvement should always provoke a search for an inherited metabolic disorder.

Viewed from another perspective, certain outstanding clinical symptoms that are more often attributable to common diseases of the adult nervous system, such as multiple sclerosis and atherosclerosis, are sometimes the result of an inborn error of metabolism. These rare instances are categorized by their main features in Table 37-8, adopted from Grey et al.

To reiterate, the aforementioned dictum that tract involvement (corticospinal, cerebellar, peduncular, sensory, optic nerve) indicates a leukodystrophy and that “gray matter” signs (seizures, myoclonus, dementia, retinal lesions) indicate a poliodystrophy is useful mainly in the early stages of a disease. Some of the lysosomal storage diseases affect both galactolipids (galactocerebrosides and sulfatides) and gangliosides; hence both white and gray matter are involved. As mentioned earlier, the paper by Turpin and Baumann is of interest when this group of diseases is viewed from the strictly psychiatric point of view.

In concluding this discussion, which classifies the inherited monogenetic metabolic diseases in accordance with their clinical characteristics, the careful reader will appreciate its artificiality. Nearly every one of the diseases of each category may present some neurologic abnormality other than the ones we have emphasized, so that the potential number of variations is almost limitless. However, the plan presented here—of thinking of these diseases in reference to age periods and syndromes—is of heuristic value and facilitates clinical study of this extremely difficult segment of neurologic medicine.
The first described and best-characterized member of this group of diseases is a symmetrical proximal myopathy that can occur as an isolated phenomenon or in combination with any one of the major mitochondrial syndromes. In 1966, Shy and coworkers described the histochemical and electron-microscopic abnormalities of the muscle mitochondria in a childhood myopathy, which they called *megacomial* (meaning marked enlargement of the mitochondria) or *pleocomial* (referring to an excessive number of mitochondria). Later this change came to be known as “ragged red fibers,” so named because of the subsarcolemmal and intermyofibrillar collections of membranous (mitochondrial) material in the type 1 (red) muscle fibers as visualized by the Gomori trichrome stain in sections of frozen muscle. This morphologic change may be an asymptomatic accompaniment of the mitochondrial disorders or, conversely, a mitochondrial disease of the CNS may exist without histologic or ultrastructural abnormalities in the muscle.

A second unifying feature of these diseases is an elevation of lactate or of the lactate-to-pyruvate ratio in the blood and CSF; this is the result of the respiratory chain abnormalities. These elevations are most prominent after exercise, infection, fever, or alcohol ingestion, and—in some conditions—are capable of inducing recurrent ketoadicotic coma, which may be the presenting manifestation of a mitochondrial disease. Leigh syndrome and MELAS particularly have a tendency to exhibit elevations of lactate; however, the diagnosis of either cannot be excluded in the presence of normal levels, even after provocation by exercise. Using phosphorus MRI scans, one can compare levels of inorganic phosphate to phosphocreatine levels in muscle; in genetic muscle diseases of several types, this ratio increases, but it is highest in those of mitochondrial origin.

Although the mitochondrial diseases are considered here as a group, individual ones are of necessity mentioned in other chapters because of their outstanding characteristics. Thus, the syndrome that combines epilepsy, deafness, and developmental delay with ragged red muscle fibers (myoclonic epilepsy with ragged red fibers, or MERRF) has been discussed in Chap. 16, on epilepsy. The syndrome of progressive external ophthalmoplegia (PEO) has been included with other abnormalities of eye movements (Chap. 50); lactic acidosis and stroke-like episodes (MELAS) were considered in Chap. 34, with the cerebrovascular diseases; and Leber hereditary optic neuropathy, with other causes of visual loss (Chaps. 13 and 39). The Leigh syndrome, a symmetrical subacute necrotizing encephalomyelopathy, usually with lactic acidosis, also has a number of complex presentations and is mentioned in the differential diagnosis of several syndromes. For each of the aforementioned diseases, wide clinical experience will bring to light an individual or a family in whom some odd syndrome has been linked to a mitochondrial disorder. Furthermore, two major syndromes may coexist in one individual and fragmentary subsyndromes are known to occur, with onset from childhood to early adult life. It serves little purpose, therefore, to catalogue all of these associations. Only the best-characterized entities, listed in Table 37-9, are described here. The most common combinations of mitochondrial syndromes have been of Kearns-Sayre syndrome with MELAS or with MERRF, progressive ophthalmoplegia with MERRF, and MERRF with MELAS.

We prefer to avoid the issue of what defines a “mitochondrial disorder”—its genetic defect, the biochemical disorder, or the clinical syndrome. The clinician assigns this term to the combination of a genetic mutation of mitochondrial DNA and certain clinical features that constitute a recognizable syndrome; the biochemical changes are taken as markers of the disordered energy-producing mechanisms of the mitochondrial machinery. Recently, mitochondrial failure has also become a focus of interest in various degenerative neurologic conditions, such as Alzheimer and Parkinson diseases, but none of the currently understood mutations of the mitochondrial genome are implicated in these conditions.

### Mitochondrial Myopathies

The mildest form of muscle disorder due to mitochondrial disease is a benign and relatively static proximal weakness that tends to be more severe in the arms. Exercise intolerance alone is reported by more than half of these patients. There are adult-onset cases, but...
careful questioning usually reveals lifelong symptoms (weakness, poor endurance, discomfort, exertional dyspnea, and tachycardia), which may be so slight and slowly progressive that the patient leads a relatively normal life for decades. Less frequent patterns of muscle disease include a fascioscapulohumeral or limb-girdle pattern of weakness as well as occasional episodes of exertional myoglobinuria. Some patients develop progressive external ophthalmoplegia (PEO) several years after the limb weakness becomes evident. Several mutations are associated with a pure or predominant myopathic syndrome, the most common one being located at position 3250 of the mitochondrial genome. Rarer variants, such as combined skeletal weakness and cardiomyopathy, are referable to other loci.

At the opposite end of the spectrum is an infantile myopathy in which weakness and lactic acidosis become evident in the first week of life and are fatal by 1 year. Many of these patients and some members of their families have a history of renal dysfunction combined with weakness of early onset. The muscle tissue shows numerous ragged red fibers, and cytochrome oxidase activity is virtually absent. DiMauro and others have described a remarkable partly reversible form, which, early on, requires ventilatory support and gastric feeding but improves clinically as the child ages; the lactic acidosis disappears by age 2 or 3 years. In these severe childhood cases, the deficiencies in cytochrome oxidase suggest a defect in mitochondrial genes, but the site has not been found.

As mentioned above, the histologic feature that unites mitochondrial myopathies is the presence of ragged red fibers. This finding points to the diagnosis of a mitochondrial disorder in any case where weakness is coupled with exercise intolerance and elevated serum lactate, particularly if there is a family history of similar problems. Also, the presence of ragged red fibers differentiates the mitochondrial myopathies from the glycogenoses, but it bears emphasizing that ragged red fibers are rare in infants and young children, even in those with confirmed mitochondrial disease.

**Progressive External Ophthalmoplegia (PEO) and Kearns-Sayre Syndrome**

(See also page 1220)

The combination of progressive ptosis and symmetrical ophthalmoplegia is a common manifestation of mitochondrial disease. Usually there is no diplopia or strabismus or at most only transient diplopia, despite slightly dysconjugate gaze. Mitochondrial abnormalities are found in the extraocular muscles of these patients. We have been impressed at how long the illness can exist before it brings the patient to a physician. To be differentiated is myasthenia gravis, which is characterized by fatigable weakness and responsiveness to cholinergic medications, neither of which is not a feature of mitochondrial disorders. In our experience, nearly all cases of PEO are due to mitochondrial disorders, but rarely the condition may be simulated by one of several genetically determined muscular dystrophies, including oculopharyngeal dystrophy and a type in which there are no other associated weaknesses but is, however, linked to facioscapulohumeral dystrophy (FSH) (Chap. 50).

Progressive external ophthalmoplegia bears a close relationship to the Kearns-Sayre syndrome of retinitis pigmentosa (onset before age 20), ataxia, heart block, and elevated CSF protein; sensory deafness, seizures, or pyramidal signs may be added (page 1220). The CNS syndromes of MELAS or MERRF (see further on) may also be combined occasionally with PEO.

**Subacute Necrotizing Encephalomyelopathy**

(Leigh Disease; SNE)

This is a familial or sporadically occurring mitochondrial disorder with a wide range of clinical manifestations. Only some of the cases display a maternal pattern of inheritance. The onset of neurologic difficulty in more than half of these patients is in the first year of life, mostly before the sixth month; but late-onset forms, with great heterogeneity of presentation as late as early adulthood, are also known. Neurologic symptoms often appear subacutely or abruptly, sometimes precipitated by a febrile illness or a surgical operation. It has seemed to us that this rapid onset is more characteristic of Leigh disease than it is of the other mitochondrial disorders.

In infants, loss of head control and other recent motor acquisitions, hypotonia, poor sucking, anorexia and vomiting, irritability and continuous crying, generalized seizures, and myoclonic jerks constitute the usual clinical picture. If the onset is in the second year, there is delay in walking, ataxia, dysarthria, psychomotor regression, tonic spasms, characteristic respiratory disturbances (episodic hyperventilation, especially during infections, and periods of apnea, gasping, and quiet sobbing), external ophthalmoplegia, nystagmus, and disorders of gaze (like those of Wernicke disease), paralysis of deglutition, and abnormal movements of the limbs (particularly dystonia but also jerky and choreiform movements). Mild cases, showing mainly developmental delay, have been mistaken for cerebral palsy. Peripheral nerves are involved in some cases (areflexia, weakness, atrophy, and slowed conduction velocities of peripheral nerves); in a few, autonomic failure is the most prominent feature. In some children the disease is episodic; in others it is intermittently progressive and quite protracted, with exacerbation of neurologic symptoms in association with nonspecific infections. The CSF is usually normal, but the protein content may be increased.

The pathologic changes take the form of a bilaterally symmetrical foci of spongy necrosis with myelin degeneration, vascular proliferation, and gliosis in the thalami, midbrain, pons, medulla, and spinal cord. The basal ganglia are characteristically but not invariably affected. Also, there may be a demyelinative type of peripheral neuropathy. In their distribution and histologic appearance, the CNS lesions resemble those of Wernicke disease (due to a deficiency of thiamine) except that the lesions of Leigh disease are more extensive—sometimes involving the striatum—and they tend to spare the mammillary bodies. The lesions, particularly those of the lenticular nuclei and brainstem, may be seen in CT scans and are strikingly demonstrated by MRI. The histochemical appearance of muscle is normal, although electron microscopy may show an increased number of mitochondria.

The clinical boundaries of Leigh disease have not been defined precisely. A familial disorder of infancy and early childhood—referred to as bilateral striatal necrosis and associated with dystonia, visual failure, and other neurologic defects—is probably a variant. The same may be true of an obscure adult-onset syndrome of progressive dementia, due to thalamic lesions, in the form of necrosis, vascular proliferation, and gliosis.

The mitochondrial gene mutation most often associated with the Leigh disease is also discussed in relation to the NARP syndrome, below. The close relationship between the two processes re-emphasizes the point that several mitochondrial mutations appear to give rise to the clinical and pathologic picture of a subacute necrotizing encephalopathy.
Neuropathy, Ataxia, Retinitis Pigmentosa Syndrome (NARP)

As just indicated, Leigh syndrome exemplifies to a remarkable degree the heterogeneity of abnormalities that may be associated with cytochrome oxidase deficiency due to a single mitochondrial gene mutation. A minor transversion error, the substitution of one amino acid in the mitochondrial DNA at position 8993, the same site implicated in Leigh syndrome, also gives rise to a maternally inherited syndrome of sensory neuropathy, ataxia, and retinitis pigmentosa (NARP). Included in some cases are developmental delay, seizures, and proximal muscle weakness. This gene abnormality creates a defective ATPase-6 of complex V of the mitochondrial respiratory chain.

The severity of the NARP syndrome corresponds to the amount of aberrant DNA in the mitochondrial genome; mutations involving over 90 percent of mitochondrial DNA produce the more severe phenotype of the Leigh syndrome (SNE). Santorelli and colleagues found that 12 of 50 patients with Leigh syndrome from 10 families displayed the 8993 point mutation. Within one kindred, the mitochondrial aberration may vary from a mild developmental delay, to NARP, to the full-blown Leigh syndrome, or early death with lactic acidosis. These differences in severity are thought to result from the mosaicism of mitochondrial genetics and specifically to the protective effect of even small amounts of the normal mitochondrial genome. The first manifestations of disease may not appear until adulthood, although it only rarely begins after age 20. The similarities to Refsum disease are discussed on page 1157.

Further confounding the clinical classification of this disease complex is the observation that many patients with the Leigh syndrome have a pyruvate dehydrogenase (usually X-linked) or pyruvate dehydrogenase deficiency or a cytochrome oxidase deficiency. These are common to many mitochondrial disorders and enzymatically deficiencies. Bridging these complex cases to the typical ones are instances with cytochrome oxidase deficiency with psychomotor retardation, slowed growth, and lactic acidosis, many without the striatal or brainstem spinal necroses of Leigh syndrome.

Congenital Lactic Acidosis and Recurrent Ketoacidosis

Certain types of organic acidemia occurring in early infancy and of unproved genetic etiology have already been mentioned (page 802). Here reference is made to those few cases that are associated with deletions of mitochondrial DNA. The syndrome consists of psychomotor regression and episodic hyperventilation, hypotonia, and convulsions with intervening periods of normalcy. Choreoathetosis or progressive ophthalmoplegia have been added in a few. Probably most cases of this type are due to disorders of the mitochondrial respiratory chain, particularly of the pyruvate-decarboxylase complex. Some children are dysmorphic, with a broad nasal bridge, micrognathia, posteriorly rotated ears, short arms and fingers, and other similar but mild dysmorphic features. De Vivo and colleagues have given a synopsis of this disease, as noted in the references. Death usually occurs before the third year. The important laboratory findings are acidosis with high lactate levels and hyperalaninemia. The few cases that have been examined postmortem are found to have necrosis and cavitation of the globus pallidus and cerebral white matter, as in SNE. The diagnosis can be made by the finding of ragged red fibers in muscle or by measurement of enzyme activity. The process must be distinguished from the several diseases of infancy that are complicated by lactic acidosis.

Myoclonic Epilepsy with Ragged Red Fiber (MERRF) Myopathy

This is perhaps the most distinctive mitochondrial disease, presenting as it does with progressive myoclonic epilepsy or myoclonic ataxia. As was noted in Chap. 6, these cases must be differentiated from several entities with a more predictable clinical course, such as juvenile myoclonic epilepsy, Unverricht-Lundborg disease, Lafora-body disease, Baltic myoclonus, and neuronal ceroid-lipofuscinosis, discussed earlier in this chapter. Tsairis and colleagues were the first to describe the connection between familial myoclonic epilepsy and mitochondrial changes in muscle, and numerous variants have been identified since their report.

In our limited experience with this disease, myoclonus in a child or young adult is the most typical feature and is elicited by startle or by voluntary movement of the limbs. The nature of the seizures varies but includes drop attacks, focal epilepsy, or tonic-clonic types, some of which are photosensitive. The ataxia tends to worsen progressively, replacing the myoclonus and seizures in some instances and remaining a minor feature in others. The myopathy usually produces inapparent or mild weakness, but the presence of mitochondrial muscle abnormalities is necessary for clinical diagnosis. To this constellation may be added any of the other elements of the mitochondrial diseases that have already been noted, including deafness (present in our cases), mental decline, optic atrophy, ophthalmoplegia, cervical lipomas, short stature, or neuropathy.

Most cases are familial and display maternal inheritance, but the age of onset may vary and affected individuals have been reported with symptoms beginning as late as the sixth decade. Almost always the patients with later onset have the mildest disease, with only myoclonic epilepsy. Conversely, those with onset in the first decade tend to be more severely affected and die before the third decade. As with the other mitochondrial processes, the quantitative burden of mutant DNA bears some relationship to the time of onset and severity of the disease. Eighty percent of patients with MERRF have a point mutation of the mitochondrial genome at locus 8344, which codes for a transfer RNA, and, conversely, most patients with this mutation will ultimately manifest some or all the clinical features of MERRF, including those with crossover features of the Leigh syndrome.

Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis, and Stroke-Like Episodes (MELAS)

Patients with this syndrome have normal early development followed by poor growth, focal or generalized seizures, and recurrent acute episodes that resemble strokes or prolonged transient ischemic attacks. The stroke deficits often improve but in some cases lead to a progressive encephalopathy. Some have hemichorial headaches that cannot be distinguished from migraine, and others suffer repetitive vomiting or episodic lactic acidosis. If there is a characteristic feature it is an unusual clinical pattern of focal seizures, sometimes prolonged, which herald a stroke and produce a unique radiographic pattern of infarction involving the cortex and imme-
diate subcortical white matter. The CT scan may also show numerous low-density regions that have no clinical correlates. Most patients have ragged red fibers, but only rarely is there weakness or exercise intolerance.

Approximately 80 percent of MELAS cases are related to a mitochondrial mutation occurring at the 3243 site of the mitochondrial gene, or, in a few instances, at an alternative locus that also codes for a segment of transfer RNA. Maternal inheritance is common, but sporadic cases are well known. In the survey conducted by Hammans and coworkers, only half of the cases of the 3243 mutation were associated with the MELAS syndrome. The finding of an abnormal mitochondrial genome in the endothelium and smooth muscle of cerebral vessels has been suggested as a basis for the strokes and migraine headaches.

The Diagnosis of Mitochondrial Disorders

The characteristic neurologic signs of a mitochondrial disorder fall into four broad groups: (1) combinations of ataxia, seizures, and myoclonus, typified by the MERRF syndrome; (2) migraine-like headaches, recurrent small strokes, and preceding seizures, typified by the MELAS syndrome; (3) ophthalmoplegia and retinitis pigmentosa with polyneuropathy, optic atrophy (Leber type), or deafness (Kearns-Sayre syndrome); and (4) a myopathy that is slowly progressive or fluctuating in severity. These may be combined with dementia, lactic acidosis, short stature, ptosis, pigmented retinal degeneration, and cardiac conduction defects (as in the Kearns-Sayre syndrome) as well as with multiple symmetrical lipomas. Peripheral nerve involvement, although common in these disorders, is usually asymptomatic; autonomic failure may be a rare manifestation. A panoply of visceral dysfunctions are at times associated with the neurologic features—including bone marrow changes of sideroblastic anemia, renal tubular defects, endocrinopathies (mainly diabetes mellitus, but also hypothyroidism or deficiency of growth hormone), hepatopathy, cardiomyopathy, and recurrent vomiting with intestinal pseudo-obstruction. Diabetes has been a marker in several of the early-onset MELAS and MERRF cases that we have seen, but less often when the first manifestations appeared in adulthood.

The investigation of a suspected case of mitochondrial disease begins with an exploration of the family history for odd childhood diseases, including neonatal death, unexplained seizure disorders, and progressive neurologic deficits of the types already described. Unexplained deafness or diabetes in family members might also raise the level of suspicion of a mitochondrial disorder. The diagnosis should be suspected when a disorder with these characteristics occurs in a pattern that indicates inheritance solely from the females in the family. That said, one encounters families with mendelian patterns of inheritance due to nuclear gene defects as described in the introductory section of this chapter. Commercial tests of leukocytes for the more frequent mitochondrial point mutation sites (3243, 8993, and 8344) are useful but reveal abnormalities in only about 15 percent of patients, perhaps somewhat higher in MERRF and MELAS, even in those whose muscles contain an abundant quantity of mutant mitochondrial genome. Resting and postexercise lactate and pyruvate determinations are helpful, but this test of aerobic capacity has limitations. The more recent work of Taivassalo and colleagues, while showing a wide range of values, suggests that measurement of the partial pressure of oxygen in venous blood from the forearm after ischemic exercise (ischemic forearm test) may still be useful in distinguishing patients with mitochondrial disease from normal subjects. In the former there is a paradoxical rise in PO2 from an average of 27 to 38 mmHg, while normals show a decline in this value.

A muscle biopsy may disclose several basic abnormalities; ragged red fibers can be recognized by use of the modified Gomori stain on frozen material, and the absence of succinate dehydrogenase and cytochrome oxidase by appropriate histochemical staining. In cases of suspected Leigh syndrome or MELAS, the CT or MRI may show some of the characteristic cerebral lesions; in the other mitochondrial disorders, there are often focal nondescript hyperintensities on T2-weighted MRI as well as atrophy, lucencies, or calcification. Sampling of chorionic villi for prenatal diagnosis may reveal mutant mitochondrial DNA, but this information is not entirely dependable.

It should be evident from the foregoing discussion that normal findings in any of these tests, including the muscle biopsy, do not exclude mitochondrial disease. In the final analysis, it is the clinical syndrome, family history, and any corroborating evidence of a mitochondrial disorder or its genetic representation that is diagnostic. Jackson and coworkers suggest that isolated phenomena such as dementia, muscle weakness, epilepsy, nervous deafness, migraine with strokes, small stature, myoclonic epilepsy, or cardiomyopathy should prompt consideration of a mitochondrial disorder when no other explanation is evident.

Subsumed under this broad heading is a diversity of both developmental malformations and diseases acquired during the intrauterine period of life. They number in the hundreds, according to the tabulation of Dyken and Krawiecki, although many are very rare. Taxonomically they make up two broad categories. The first includes many unrelated genetic pathologic processes: some stem from germplasm abnormalities; others are associated with triplication, deletion, and translocations of chromosomes; and probably some are inherited on a polygenic basis. A remarkable accomplishment has been the identification in the past several years of specific gene defects that give rise to malformations of the brain. The second category is composed of the effects of a variety of noxious agents acting at different times on the immature nervous system, i.e., during the embryonal, fetal, and paranatal periods of life.

It would be intellectually satisfying if all the states that originate in the intrauterine period could be separated strictly into genetic (hereditary) or nongenetic forms, but in many instances the biologic information and the pathologic changes in the brain at this early age do not allow such a division. For example, among the many diseases in which the neural tube fails to close (rachischisis), more than one member of a family may be affected; but it cannot be stated whether a genetic factor is operative or an exogenous factor, such as folic acid deficiency, has acted on several members during a succession of pregnancies of one mother. Even what appears to be an outright malformation of the brain may be no more than a reflection of the timing of an exogenous process that has affected the nervous system and other organs early in the embryonal period, derailing later processes of development. Teratology, the scientific study of neurosomatic malformations, is replete with such examples.

Several points should be noted regarding the frequency of developmental disorders. Smith (see K. L. Jones) points out that a single malformation, usually of no clinical significance, occurs in 14 percent of newborns. Two malformations appear in 0.8 percent, and in this group, a major defect is five times more frequent than in the normal population. Three or more malformations are found in 0.5 percent of newborns, and in this latter group, more than 90 percent have one or more major abnormalities (defined as structural abnormalities of prenatal origin that seriously interfere with viability or physical well-being). The figures for major congenital malformations, compiled by Kalter and Warkany, are somewhat higher. What is most important for the neurologist is the fact that the nervous system is involved in most of these infants with major malformations. In fact, about 40 percent of deaths during the first postnatal year are in some manner related to prenatal malformations of the central nervous system (CNS).

A perusal of the following pages makes it evident that there is a great variety of structural defects of the nervous system in early life; in fact, every part of the brain, spinal cord, nerves, and musculature may be affected. Furthermore, certain principles are applicable to the entire group of developmental brain disorders. First, the abnormality of the nervous system is frequently accompanied by an abnormality of some other structure or organ (eye, nose, cranium, spine, ear, and heart), which relates them chronologically to a certain period of embryogenesis. Conversely, the presence of these malformations of nonnervous tissues suggests that an associated abnormality of the nervous system is developmental in nature. This principle is not invariable; in certain maldevelopments of the brain, which must have originated in the embryonal period, all other organs are normal. One can only assume that in this instance the brain was more vulnerable than any other organ to prenatal as well as natal influences. Perhaps this occurs because the nervous system, of all organ systems, requires the longest time for its development and maturation, during which it is susceptible to disease. Second, a maldevelopment of whatever cause should be present at birth and remain stable thereafter, i.e., be nonprogressive (in contrast to the majority of metabolic diseases of infancy discussed in the preceding chapter). Again, this principle requires qualification—the abnormality may have affected parts of the brain that are not functional at birth, so that an interval of time must elapse postnatally before the defect can express itself. Third, for an abnormality to be characterized as developmental, birth should have been nontraumatic and the pregnancy uncomplicated by infection or other injurious event. Conversely, the occurrence of a traumatic birth is not proof of a causative relationship between the injury (or infection) and the abnormality, because a defective nervous system may itself interfere with the birth or the gestational process. Fourth, if the congenital abnormality has occurred in other members of the family of the same or previous generations, it is usually genetic—although, as noted above, this does not exclude the possible adverse effects of exogenous agents. Fifth, many of the teratologic conditions that cause birth defects pass unrecognized because they end in spontaneous abortions. For example, defects due to chromosomal abnormalities occur in about 0.6 percent of live births, but such defects are found in more than 5 percent of spontaneous abortions at 5 to 12 weeks gestational age. Sixth, low birth weight and gestational age, indicative of premature birth, increase the risk of mental subnormality, seizures, cerebral palsy, and death.

Regarding etiology, which is really the crux of the problem of birth defects, some order and classification have emerged. In general, malformations may be subdivided into four groups: (1) one in which a single mutant gene is responsible (2.25 per 1000 live births); (2) one in which birth defects are associated with chromosomal aberrations (duplication, breakage); (3) a group comprising defects attributable solely to exogenous factors (a virus or other infectious agent, irradiation, or toxin); and (4) the largest group of all, 60 percent of cases, in which no cause can be identified.

It has been stated that true malformations are due to fundamental endogenous disturbances of cytogenesis and histogenesis occurring in the first half of gestation and that exogenous factors, which destroy brain tissue but do not cause malformations, operate in the second half. The potential fallacy of this division is obvious. An exogenous lesion occurring during the embryonal period may not only destroy tissue but also derail the neuronal migrations of normal development.
A textbook on principles of neurology is not the place in which to present a detailed account of all the hereditary and congenital developmental abnormalities that might affect the nervous system. For such details, the interested reader should refer to several excellent monographs. Three that the authors recommend are Berg’s Principles of Child Neurology, and Lyon and Evrard’s Neuropediatrie. These are supplemented by special atlases of congenital malformations mentioned further on. In this chapter we sketch only the major groups and discuss in detail a few of the more common disease entities. The classification in Table 38-1 adheres to a grouping in accordance with the main presenting abnormality or abnormalities. Represented here are the common problems that lead families to seek consultation with the pediatric neurologist: (1) structural defects of the cranium, spine, and limbs, and of eyes, nose, ears, jaws, and skin; (2) disturbed motor function—taking the form of retarded development or abnormal movements; (3) epilepsy; and (4) mental retardation. The following discussion focuses on each of these clinical states.

**NEUROLOGIC DISORDERS ASSOCIATED WITH CRANIOSPINAL DEFORMITIES**

A majority of the disorders in this group are due to a genetic error, including those with a specific chromosomal abnormality, or to some unknown factor. One has only to walk through an institution for the mentally retarded to appreciate the remarkable number and diversity of physical disfigurements that attend abnormalities of the nervous system. Smith, in the third edition of his monograph on the patterns of human malformations, listed 345 distinctive syndromes; in the fourth edition (edited by K. L. Jones, 1988), many new ones were added. Indeed, a normal-appearing and severely retarded individual stands out in such a crowd and will frequently be found to have an inherited metabolic defect or birth injury.

The intimate relationship between the growth and development of the cranium and that of the brain deserves comment. In embryonic life the most rapidly growing parts of the neural tube induce special changes in and at the same time are influenced by the overlying mesoderm (a process known as induction); hence abnormalities in the formation of skull, orbits, nose, and spine are regularly associated with anomalies of the brain and spinal cord. During early fetal life the cranial bones and vertebral arches enclose and protect the developing brain and spinal cord; throughout the period of rapid brain growth, as pressure is exerted on the inner table of the skull, the latter accommodates to the increasing size of the brain. This adaptation is facilitated by the membranous fontanelles, which remain open until maximal brain growth has been attained; only then do they ossify (close).

In addition, stature is controlled by the nervous system, as shown by the fact that a majority of mentally retarded individuals are also stunted physically to a varying degree. Thus disorders of craniovertebral development assume importance not merely be-

cause of the physical disfigurement but also because they often reflect an abnormality of the underlying brain and spinal cord, i.e., they become diagnostic signs.

**Cranial Malformations at Birth and in Early Infancy**

Certain alterations in size and shape of the head in the infant, child, or even adult always signify a pathologic process that affected the brain before birth or in early infancy. The size of the cranium reflects the size of the brain; therefore the tape measure is one of the most useful tools in pediatric neurology—no examination in a neurologically affected child is complete without a measurement of the circumference of the head. Graphs of the head circumference in males and females from birth to 18 years of age have been compiled by Nellhaus. A newborn whose head circumference is below the third percentile for age and sex and whose fontanels are closed may be judged to have a developmental abnormality of the brain. A head that is normal in size at term but fails to keep pace with body length (microcephaly) reflects a later failure of growth and maturation of the cerebral hemispheres (microencephaly).

**Enlargement of the Head (Macrocephaly)** This can be due to factors extrinsic to the brain, such as hydrocephalus and hydranencephalus (as defined below), or excessive brain growth (megalo- or macroencephaly) (Table 38-2). The **hydrocephalus head** is distinguished by several features—frontal protuberance, or bossing; a tendency for the eyes to turn down so that the sclerae are visible between the upper eyelids and iris (sunset sign); thinning of the scalp and prominence of scalp veins; separation of the cranial sutures; and a “cracked pot” sound on percussion of the skull. Infantile hydrocephalus usually comes to medical attention because of an expanding cranium that exceeds normal dimensions for age. The usual causes are type II Chiari malformation, hereditary aqueductal stenosis, and prenatal infections, e.g., toxoplasmosis. These disorders are discussed further on.

The **hydranencephalic head** (hydrocephalus and destruction or failure of development of parts of the cerebrum) is often associated with enlargement of the skull. When it is transilluminated with a strong flashlight in a darkened room, the fluid-filled region of the cranium glows like a jack-o’-lantern. Hydranencephaly is not a well-defined entity. It can be caused by cerebral infarction from intraventricular vascular occlusion or by diseases such as toxoplasmosis and cytomegalovirus (CMV) disease, which destroy parts of each cerebral hemisphere. The lack of brain tissue reduces resistance to intraventricular pressure, permitting great enlargement of both lateral ventricles; it is especially marked if there is an added hydrocephalic state due to interference with cerebrospinal fluid (CSF) circulation. This type of destruction of the cerebral mantle in the embryonal period may lead to the formation of huge defects, with apposition of ventricular and pial surfaces (porencephaly) and subsequent failure of development (evagination) of the brain. Yakovlev and Wadsworth referred to the localized failure of evagination as schizencephaly and postulated that it was the result of a focal developmental defect in the wall of the cerebral mantle. They based their interpretation on the finding of malformed cortex in the margins of the defect, but this might indicate only that the lesion preceded neuronal migration. Levine and coworkers have attributed it to a destructive, possibly ischemic lesion occurring in the first few weeks of gestation, at a time when neuronal migration was incomplete. We favor the latter explanation and describe it further in relation to the cerebral palsies. In either event, the lack of resistance of the defective cerebral mantle to ventricular pressure expands the brain and cranium.

The **macrocephalic head** (a large head with normal or only slightly enlarged ventricles) may be indicative of an advancing metabolic disease that enlarges the brain, as in Alexander disease, Canavan’s spongy degeneration of infancy, and later phases of Tay-Sachs disease, all of which are described in Chap. 37. Agenesis of the corpus callosum, a common congenital defect, may be associated with macrocephaly and varying degrees of mental impairment, optic defects, and seizures. In a series of 56 patients with agenesis of the corpus callosum, Taylor and David reported the presence of epilepsy in 32 and varying degrees of mental retardation in 28; only 9 had no recognizable neurologic defects. Also noted was a high incidence of psychiatric disturbances in these patients. In such cases, computed tomography (CT) and magnetic resonance imaging (MRI) reveal the characteristic “bat-wing” deformity of the ventricles. There is also asynchrony of electrical activity of the two cerebral hemispheres on the electroencephalogram (EEG). In a few of these patients, an autosomal dominant inheritance has been found (Lynn et al). Agenesis of the corpus callosum is also part of the Aicardi syndrome (see further on) and the Andermann syndrome, and it has been noted in some cases of nonketotic hyperglycinemia.

**Subdural hematomas** may also enlarge the head and cause bulging of the fontanels and separation of the sutures. In the latter condition, the infant is usually irritable and listless, taking nourishment poorly. Infants and children with neurofibromatosis, osteogenesis imperfecta, and aandroplasia also have enlarged heads; in the last condition some degree of hydrocephalus appears to be responsible. Ultrasonography, which can be performed in the prenatal and neonatal periods, is usually diagnostic in all these cranial enlargements. Also MRI and CT scanning will disclose the size of the ventricles and the presence of subdural blood or fluid (hygroma). Apart from patients with these pathologic states, there are individuals whose heads and brains are enlarged but who are normal in all other respects. Many of these individuals come from families with large heads; Schreier and colleagues, who traced this condition through three generations of some families, declared it to be an autosomal dominant trait. This group represented 20 percent of 557 children referred to a clinic because of cranial enlargement (Lorber and Priestley).

**Hemimegalencephaly** This term refers to a marked enlargement of one cerebral hemisphere as a result of a developmental abnormality. The cortical gray matter and sometimes the basal ganglia are greatly increased in volume and weight. The cerebellum, brain-

</table>
stem, and spinal cord retain their normal dimensions. The cranium may be misshapen or enlarged but is normal in size in some cases. Rarely, the face and body are enlarged on the side of the enlarged hemisphere. The cortex of the giant hemisphere is thick and disorganized. Neurons are in disarray and some are enlarged; in some places the natural lamination of the cortex is effaced. Nothing is known about causation, but apparently embryogenesis has been deranged at the stage of neuroblast formation.

Clinically, most affected individuals have been mentally retarded and some are epileptic. A degree of hemiparesis may be present, but severe hemispheric neurologic deficits are generally not reported. The hemimegalencephaly has been discovered at autopsy in a few individuals who had no mental or neurologic deficits.

**Craniostenoses** Some of the most startling cranial deformities are caused by premature closure of the cranial sutures (membranous junctions between bones of the skull). Such conditions are estimated to occur in 1 of every 1000 births, with a predominance in males (Lyon and Evrard). The growth of the cranial is inhibited in a direction perpendicular to the involved suture(s), with a compensatory enlargement in other dimensions, as allowed by the patent sutures. For example, when the lambdoid and coronal sutures are both affected, the thrust of the growing brain enlarges the head in a vertical direction (tower skull, or oxycephaly, also referred to as turriccephaly and acrocephaly). The orbits are shallow, the eyes bulge, and skull films show islands of bone thinning (Lückenschadel). When only the sagittal suture is involved, the head is long and narrow (scaphocephaly), and the closed suture projects, keel-like, in the midline. With premature closure of the coronal suture, the head is excessively wide and short (brachycephaly). The nervous system is usually normal in these restricted craniostenoses. If this condition is recognized before 3 months of age, the surgeon can make artificial sutures that may permit the shape of the head to become more normal (Shillito and Matson). Once brain growth has been completed, little can be done aside from complex reconstructive surgery. When several sutures (usually coronal and sagittal) are closed, so as to diminish the cranial capacity, intracranial pressure may increase, impairing cerebral function and causing headache, vomiting, and papilledema. Obviously an operation is then needed to increase the capacity of the skull.

In acrocephalosyndactyly or Apert syndrome, craniostenoses that are combined with syndactyly (fused, or webbed, fingers or toes), there are often added complications—mental retardation, deafness, convulsions, and loss of sight secondary to papilledema. The so-called clover-shaped skull is the most severe and lethal of the craniostenoses because of the associated developmental anomalies of the brain (see further on).

When, for any reason, an infant lies with the head turned constantly to one side (because of a shortened sternomastoid muscle or hemianopia, for example), the occiput on that side becomes flattened, as does the opposite frontal bone. The other occipital and frontal bones bulge, so that the maximum length of the skull is not in the sagittal but in the diagonal plane. This condition is called plagiocephaly, or wry head. Craniostenosis of one-half of a coronal suture may also distort the skull in this way.

**Figure 38-1. MRI in the coronal plane in an infant with seizures. Deep in the white matter, adjacent to the lateral ventricle, is a large heterotopic aggregate of gray matter. Also, there appears to be an increased infolding of the cerebral cortex (polymicrogyria).**

**Disturbances of Neuronal Migration**

Neuroembryologic studies have identified several milestones of neuroblast formation, migration, cortical organization, neuron differentiation, and connectivity. Certain developmental anomalies have been traced to one or another of these stages of cytogenesis and histogenesis in the first trimester of gestation and to the growth and differentiation that take place in the second and third trimesters. During the first trimester of gestation, postmitotic neurons that will ultimately reside in the cortex arise in the ventricular zone adjacent to the ventricles. They then migrate along the scaffold of radial glia to form the multilayered cortex. It is striking that neurons moving up the scaffold must pass through neurons that are already in position in the cortex, leading to an “inside-out” lamination in which the most recently born and arrived neurons reside on the outermost surface of the forming cortex.

Originally there is an excess of neurons, many of which degenerate during development—a process properly called apoptosis. There are recorded instances in which the full complement of neuroblasts and neurons fails to be generated. Or the emergence of two separate cerebral hemispheres may not occur (holoprosencephaly), or the bihemispherical brain may remain small (microcephaly). In other described specimens, a diminished number of neurons is less obvious than their failure to migrate to the cortical surface; they remain scattered through the mantle zone in sheets and heterotopic aggregates. One type of focal band-shaped subcortical heterotopia is termed “double-cortex”. Micropolysgyria refers to an excessive number of abnormally small gyri. It is expressed by a syndrome of mental retardation, seizures, delayed speech, and motor abnormalities. Or, the cortex may fail to become sulcated—i.e., it is lissencephalic or may be defectively convoluted, forming microgyric and pachygyric (broad gyral) patterns. In yet other brains, neuronal migration is normal for the most part, but small groups of neurons in particular regions may lag or present in regional heterotopias (focal dysgeneses) (Fig. 38-1). These migrational disorders, particularly these heterotopias, are just now being recognized by MRI and are found to have a possible functional significance in such states as mental retardation, epilepsy, and dyslexia. Finally, the cortex may be normally formed and structured but there is a failure of differentiation of intra- and intercor-
tical and interhemispheral connections, the most obvious one being agenesis of the corpus callosum.

The conjunction of cardiac, limb, gut, and bladder abnormalities with neurologic disorder indicates the time at which the insult takes place: cardiac abnormalities occur between the fifth and sixth week; extroversion of the bladder at less than 30 days; duodenal atresia, before 30 days; syndactyly, before 6 weeks; meningocele, before 28 days; anencephaly, before 28 days; cleft lip, before 36 days; syndactyly, cyclopia, and holoprosencephaly, before 23 days.

With these elementary facts of neuroembryology in mind, the bases of the following clinical states are readily conceptualized: anencephaly, lissencephaly, holoprosencephaly, polymicrogyria and pachygyria, microcephaly, and special combinations of cranial and somatic abnormalities. Each is described below.

Also in regard to disorders of brain development, there are special types of tumors thought to be the consequence of abnormal neuronal or glial development; they should be mentioned here. They are variously termed gangliomas, dysembryoblastic neuroepitheliomas, and low-grade astrocytomas. Often they become manifest in the first year of life or even before birth. Their relatively slow growth and benign character suggest that some of them represent hamartomas rather than true neoplasms (see Chap. 31).

Some of the aforementioned cranial abnormalities, of which microcephaly is the most frequent, are secondary to anomalies of cerebral growth. Others—such as abnormalities of the eyes, root of nose, upper lip, ears, and limbs—may represent part of the basic developmental disorder.

**Genetics of Cerebral Disorders of Neuronal Migration** (Table 38-3) Since each phase of cerebral development is under genetic control, it comes as no surprise that aberrant development might also be genetic. The singular advance in this field has been the identification in recent years of large numbers of genetic defects that underlie the disorders of neuronal migration. These mutations, and what are known of their effects on the developing nervous system, have been reviewed extensively by Mochida and Walsh, by Kato and Dobyn, and by Ross and Walsh; a summary of the genes is given in Table 38-3. The reader will notice that several quite different genes may give rise to the same type of maldevelopment, but in many cases the role of the affected gene corresponds to a stage and function in brain development that makes the malformation understandable. The specific genetic errors are discussed in each of the sections below. It should at the same time be noted that metabolic disturbances may give rise to malformations of cerebral development. For example, in their review of the inborn errors of metabolism that are linked to cerebral dysgeneses. Nissenkorn and colleagues point out that such disorders as Zellweger syndrome and disorders of fatty oxidation that lead to aberrant neuronal migration and to PKU, hyperglycinemia, and pyruvate dehydrogenase deficiency cause dysgenesis of the corpus callosum.

**Anencephaly** This is one of the most frequent and also most appalling congenital malformations of the brain. Its incidence is 0.1 to 0.7 per 1000 births, and females predominate in ratios ranging between 3 and 7 to 1. The concordance rate is low, being the same in identical and fraternal twins, but the incidence of the malformation is several times the expected rate if one child in the sibship has already been afflicted. Anencephaly is also more frequent in certain geographic areas, e.g., Ireland, for which various explanations of population genetics or environmental exposure have been postulated. Lacking in cases of anencephaly are large portions of scalp, cranial bones, and brain, including both cerebral cortex and white matter. All that is seen is a hemorrhagic nubbin of nerve, glial, and connective tissue. Brainstem, cerebellum, and spinal cord are present, but often they too are malformed, as are the heart and other organs (15 to 40 percent of cases). In anencephalics who survive for a few days (65 percent die in utero and almost 100 percent before the end of the first postnatal week), starle reactions may be observed, as well as movements of limbs, spontaneous respirations, pupillary light reactions, ocular movements, and corneal reflexes. In a few, avoidance reactions, crying,

</table>
and feeding reflexes can be elicited, indicating that only the rudimentary brain structures are required for these functions.

This condition can be anticipated if the mother's serum levels of α-fetoprotein and acetylcholine esterase are elevated—even more reliably, they are elevated in the amniotic fluid. Positive tests should lead to ultrasound imaging of the fetus. Hydramnios is common. Apparently, the causes of anencephaly are multiple and include chromosomal abnormalities, maternal hyperthermia, and deficiencies of folic acid, zinc, and copper (see Medical Task Force on Anencephaly in the References). Of these, there is fairly secure evidence that supplemental intake of folic acid during the first trimester of pregnancy (i.e., from the time of conception) greatly reduces the incidence of anencephaly (and of myelomeningocele).

There are additional comments on anencephaly further on in this chapter in the section on rachischisis (lack of fusion of the neural tube).

Lissencephaly (Agyria), Holoprosencephaly, and Gyral Malformations Included under this heading are several forms of neuronal migratory defects. In the lissencephalies, cortical convolutions may be absent altogether and there is morphologic evidence of several types of neuroblast deficiency resulting from either generalized or restricted forms of neuronal migration. Such cases are of particular interest to neonatologists because of their associated physical abnormalities. The degree of impairment of neurologic function seldom allows longevity, so that relatively few examples are to be found in institutions for the mentally retarded. Seizures, poor temperature regulation, failure to accept nourishment, and apneic attacks combine to shorten life. The failures of neuronal migration are of varying degrees of severity. There may be a failure of neurons to form or to migrate along glial guidelines in order to reach the more superficial layers of the cortex (Bielchowsky type); or the cortex, meninges, and eyes may fail to differentiate normally except for the dentate gyrus and hippocampus (Walker-Warburg type); or there may be other relatively minor focal derangements of cortical migrations and laminations with heterotopias of neurons in the white matter.

In the complete lissencephalies, the lateral and third ventricles enlarge due to a lack of the normal quantities of surrounding cerebral tissue (i.e., the aforementioned hydranencephaly). The cerebellar cortex is also abnormal. In some lissencephalic brains, there is slight sulcation presenting as abnormally broad or narrow convolutions, with thick, poorly laminated cortex; these are called pachgyrias or microgyrias, respectively, but the fundamental migratory abnormality is basically the same. The cerebellum is also abnormal with hypoplasia or aplasia involving the vermis and/or neocerebellum.

In the severe migratory defects, the cranium is small at birth. In one type, which is inherited as an autosomal recessive trait, there are subtle craniofacial features (short nose, small mandible, ear abnormalities) as well as congenital heart disease. In another group, there is an associated familial congenital muscular dystrophy, placing the case between the Fukuyama and Walker-Warburg syndromes (see page 1224). Most severe migratory disorders are sporadic, and the infants seldom survive for long.

Alobar and lobar holoprosencephalies are other examples of neuronal migratory defects with craniofacial abnormalities in which development has gone awry in the fifth and sixth weeks of gestation (see Volpe). In these subtypes, the two cerebral hemispheres, either totally or only in part, form as a single telencephalic mass. In nearly every case the cerebral defect is expressed by a single eye (cyclopia) and absence of nose, imparting an astonishing appearance, which is diagnostic.

In a few of the foregoing malformations, a congenital infection with CMV or rubella has been implicated (Hayward et al).

The Dandy-Walker syndrome represents a more restricted form of migration and neural tube defect. Here, there is vermician hypoplasia with or without hydrocephalus and, in some cases, an added agenesis of the corpus callosum with cerebral cortical dysgeneses (Landrieu). This defect, which is identified by the cystic enlargement of the fourth ventricle, is discussed further on, with the dysraphic neural tube defects.

That some instances of lissencephaly have a genetic basis has already been mentioned (see Table 38-3). Two genes that modify microtubular function have been identified as causes of lissencephaly: LIS1 and "doublecortin" or DCX. Large chromosomal deletions that span LIS1 cause Miller-Dieker syndrome, in which lissencephaly is associated with distinctive facial abnormalities; small defects in the same gene cause only lissencephaly. Lissencephaly with cerebellar hypoplasia is caused by mutations in the human "reelin" gene (RELN), the analogue of the defective gene in reelin mice (which show a reeling gait and abnormal cortical neuronal laminatation). Defects in the transcription factor ARX are associated with X-linked lissencephaly, agenesis of the corpus callosum, and hypogonadism. Periventricular nodular heterotopia is caused by another gene defect, filamin A gene on the X chromosome.

Microcephaly In the above-mentioned cerebral dysplasias, the cranium and brain are small, but there is also a primary form of hereditary microcephaly, called microcephaly vera, in which the head is astonishingly reduced in size (circumference less than 45 cm in adult life—i.e., 5 standard deviations below the mean). In contrast, the face is of normal size, the forehead is narrow and recedes sharply, and the occiput is flat. Stature is usually moderately reduced. Such individuals can be recognized at birth by their anthropoid appearance and later by their lumbering gait, extremely low intelligence, and lack of communicative speech. Vision, hearing, and cutaneous sensation are spared. In one of our colleagues' cases, by laborious effort using operant conditioning, it was possible to teach the patient the shapes of simple figures. (His sister's brain, examined by R. D. Adams, was malformed and weighed only 280 g.) In such cases the tendon reflexes in the legs are brisk, and the plantar reflexes may be extensor. Skull films show that the cranial sutures are present, as are convolutional markings on the inner table.

The brain often weighs less than 300 g (normal adult range, 1100 to 1500 g) and shows only a few primary and secondary sulci. The cerebral cortex is thick and un laminated and grossly deficient in neurons. In a few reported cases, there has been an associated cerebellar hypoplasia or an infantile muscular atrophy. Lesser degrees of microencephaly have been associated with progressive motor neuron disease and degeneration of the substantia nigra (Halpern et al).

Evvard and associates have described another rare, special type of microcephaly, which they call "radial microbrain." Birth is at term, but the infant dies in the first month of postnatal life. The sulcal pattern is normal, and neuronal arrangements in the cerebral cortex are normal as well. The defect appears to be in the small number of neurons that are generated, not in their migration.

Disorders of the Pial Surface This category of maldevelopment is characterized by inappropriate migration of neurons to the pial
surface, leading to a nodularity of the surface described as a cobbledstone appearance. In the three disorders with this pathologic finding, the clinical picture is one of mental retardation conjoined with congenital muscular dystrophy. Three identified gene defects are thought to alter the glycosylation of critical proteins in the brain and in skeletal muscle. These genes include the gene fukutin in Fukuyama muscular dystrophy (page 1224), the POMGNT1 gene in muscle-eye-brain disease, and the POMT1 gene in Walker-Warburg syndrome (page 1224) as summarized in Table 38-3.

Combined Cerebral, Cranial, and Somatic Abnormalities

As has been remarked, many diseases that interfere with cerebral development also deform the cranial and facial bones, eyes, nose, and ears. Such somatic stigmata therefore assume significance as indicators of altered cerebral structure and function. Moreover, they constitute irrefutable evidence that the associated neural abnormality is in the nature of a maldevelopment, either hereditary or the result of a disease acquired during the intrauterine period.

There are so many cerebro-somatic anomalies that one can hardly retain visual images of them, much less recall all the physicians’ names by which they are known. Of necessity one turns to atlases, one of the best of which has been compiled by Holmes and colleagues and is based on clinical material drawn in large part from the Fernald School and Eunice K. Shriver Center in Massachusetts. The reader may also turn to the books by Gorlin and colleagues and by Jones for specific information. Ford’s Diseases of the Nervous System in Infancy, Childhood, and Adolescence is still a valuable reference, as is Jablonski’s Dictionary of Syndromes and Eponymic Diseases.

There is some advantage in grouping these anomalies according to whether the extremities, face, ears, and skin are associated with a cerebral defect. The sheer number and variety of these anomalies permit only an enumeration of the more common ones and their most obvious physical characteristics. To identify a particular anomaly, one must turn to the specialized monographs and atlases mentioned above. Unfortunately, apart from certain genetic linkages, no useful leads as to their origin have been forthcoming.

The Syndactylic-Craniofacial Anomalies (Acrocephalosyndactyly) Commonly, fusion of two fingers or two toes or the presence of a tab of skin representing an extra digit may be seen at birth in an otherwise normal individual. However, as pointed out above, when syndactylism is of more severe degree and is accompanied by premature closure of cranial sutures, the nervous system usually proves to be abnormal as well. The general term acrocephalosyndactyly is used to describe the several combinations of craniosenosis and facial deformities and fusion of digits. Several of these disorders are a consequence of mutations in genes encoding one of two fibroblast growth factors or proteins related to them. The following descriptions include only the major features; most have, in addition, distinctive malformations of the orbits, ears, and palate.

1. Acrocephalosyndactyly types I and II (typical and atypical Apert syndrome). Turri-brachycephalic skull, syndactyly of hands and feet (“mitten hands,” “sock feet”), moderate to severe mental retardation.
3. Acrocephalo-syndactyly IV (Pfeiffer syndrome). Turri-brachycephaly; broad, enlarged thumbs and great toes; partially flexed elbows (radiohumeral or radioulnar synostoses); mild and variable mental retardation; autosomal dominant inheritance.
4. Acrocephalopolysyndactyly V (Carpenter syndrome). Premature fusion of all cranial sutures with acrocephaly, flat bridge of nose, medial canthi displaced laterally, excess digits and syndactyly, subnormal intelligence.
5. Acrocephalosyndactyly with absent digits. High, bitemporally flattened head; absent toes and syndactylic fingers; moderate mental retardation.
6. Acrocephaly with cleft lip and palate, radial aplasia, and absent digits. Microbrachycephaly due to craniosenosis, cleft lip and palate, absent radial bones, severe mental retardation.
7. Dyschondroplasia, facial anomalies, and polysyndactyly. Keel-shaped skull and ridge through center of forehead (metopic suture), short arms and legs, postaxial polydactyly and short digits, moderate mental retardation.

In all the foregoing types of syndactylism and cranial abnormality, which may be regarded as variants of a common syndrome, the diagnosis can be made at a glance because of the deformed head, protuberant eyes, and abnormal hands and feet. The degree of mental retardation proves to be variable, usually moderate to severe, but occasionally intelligence is normal or nearly so. The brain has been examined in only a few instances and not in a fashion to display fully the type and extent of this developmental abnormality.

Other Craniocephalic-Skeletal Anomalies Members of this group have distinctive anomalies of the cranium, face, and other parts, but craniosenosis is not a consistent feature.

1. Craniofacial dysostosis (Crouzon syndrome). Variable degrees of craniosynostosis; broad forehead with prominence in the region of the anterior fontanel region; shallow orbits with proptosis; midline facial hypoplasia and short upper lip; malformed auditory canals and ears; high, narrow palate; moderate mental retardation. As noted above, a genetic defect in one of the fibroblast growth factor receptors is responsible for about one-third of cases that are not associated with other deformities (Moloney et al). Autosomal dominant inheritance is seen in most cases.
2. Median cleft facial syndrome (frontonasal dysplasia; hypertelorism of Greig). Widely spaced eyes, broad nasal root, cleft nose and premaxilla, V-shaped frontal hairline, heterotypic anterior fontanel (midline cranial defect); mild to severe mental retardation.
3. Chondrodysplasia calcificans congenita (chondrodysplasia punctata, Conradi-Hiérmann syndrome). Prominent forehead; flat nose; widely separated eyes; short neck and trunk with kyphoscoliosis; dry, scaly, atrophic skin; cicatricial alopecia; irregularly deformed vertebral bodies; mental retardation infrequent. Severe shortening of limbs in some cases.
4. Orofaciodigital syndrome. All the patients are female. Pseudoclefts involving the mandible, tongue, maxilla, and palate;
hypertrophied buccal frenuli; hamartomas of tongue; sparse scalp hair; subnormal intelligence in one-half of cases.

5. **Pyknody sostosis.** Large head and frontal-occipital bossing, underdeveloped facial bones, micrognathia, unerupted and deformed teeth, dense and defective long bones with shortened limbs, short and broad terminal digits of fingers and toes, mental retardation in one-quarter of the cases.

6. **Craniotubular bone dysplasias and hyperostoses.** Included under this title are several different genetic disorders of bone, characterized by modeling errors of tubular and cranial bones. Frontal and occipital hyperostosis, overgrowth of facial bones, and widening of long bones occur in various combinations. Hypertelorism, broad nasal root, nasal obstruction, seizures, visual failure, deafness, prognathism, and retardation of growth are the major features.

**Oculoencephalic (Crano-Occular) Defects**

In this category of anomalies, there is simultaneous failure or imperfect development of eye and brain. One member of this group, the oclocerebrorenal syndrome of Lowe, has already been mentioned on page 812, and, of course, a number of the mucopolysaccharidoses are characterized by corneal opacities, skeletal changes, and psychomotor regression. Also, congenital syphilis, rubella, toxoplasmosis, and CMV inclusion disease may affect retina and brain; hypoxia at birth requiring treatment with oxygen may injure the brain and lead to retrolental fibroplasia. The true developmental defects in this group are as follows:

1. **Anophthalmia with mental retardation.** Sex-linked recessive. Absent eyes; orbits and maxillae remain underdeveloped, but adnexal tissues of eyes (lids) are intact; subnormal intelligence. Some cases of anophthalmia have been ascribed to genes encoding transcription factors that play a role in the development of the neuraxis (SOX2, RAX, RAX6).

2. **Norie disease.** Also sex-linked recessive; some sight may be present at birth; later, eyes become shrunken and recessed (phthisis bulbi); some have short digits, outbursts of anger, hallucinations, and possibly regression of psychomotor function. A novel gene, norrin, on the X chromosome has been implicated.

3. **Oculocerebral syndrome with hypopigmentation.** Autosomal recessive with absence of pigment of hair and skin; small, cloudy, vascularized corneas and small globes (microphthalmia); marked mental retardation; athetotic movements of limbs.

4. **Microphthalmia with corneal opacities, eccentric pupils, spasticity, and severe mental retardation.**

5. **Aicardi syndrome with ocular abnormality.** Chorioretinopathy, retinal lacunae, staphyoma, coloboma of optic nerve, microphthalmos, mental retardation, infantile spasms and other forms of epilepsy, agenesis of corpus callosum, and cortical heterotopias. The “bat-wing” deformity of the third and lateral ventricles on MR images and asynchronous burst-suppression discharges and sleep spindles are diagnostic. The condition is found only in females.

6. **Lissencephaly of the Walker-Warburg type.** This anomaly has already been mentioned, as has its association with congenital muscular dystrophy. Autosomal recessive inheritance. Ocular lesions are constant but variable (retinal dysplasia, microphthalmia, coloboma, cataracts, corneal opacities). There may be hydrocephalus, and by CT scans or MRI, the lack of cerebral sulci (lissencephaly) is disclosed. The abnormal eyes and orbits and absence of cerebellar vermis are diagnostic (see Table 38-3).

7. **Congenital tapetoretinal degeneration (Leber amaurosis).** Visual loss from birth, moderate to severe mental retardation, and microcephaly. Early onset of blindness and absent electrical potentials on the electroretinogram (ERG) distinguish it from later-onset Leber optic atrophy.

8. **Septo-optic dysplasia (de Morsier syndrome).** Diminished visual acuity, small optic discs, absence of septum pellucidum, and precocious puberty. Varying degrees of pituitary insufficiency may be present, requiring endocrine replacement.

**Oculoauriculocephalic Anomalies**

These are less important from the neurologic standpoint, and mental retardation is present only in some cases.

1. **Mandibulofacial dysostosis (Treacher-Collins syndrome, Franceschetti-Zwahlen-Klein syndrome).**

2. **Oculoauriculovertebral dysplasia (Goldenhar syndrome).**

3. **Oculomandibulodysecephaly with hypotrichosis (Hallermann-Streiff syndrome).**

**Dwarfism**

Midgets are abnormally small but perfectly formed people of normal intelligence; they differ from dwarfs, who are not only very small but whose bodily proportions are markedly abnormal. They may or may not be mentally normal. A majority of mentally retarded patients fall below average for height and weight, but there is a small group whose fully attained height is well below 135 cm (4 1/2 ft) and who stand apart by this quality alone (see K. L. Jones for Smith’s classification of dwarfs).

1. **Nanocephalic dwarfism (Seckel bird-headed dwarfism).** The uncompromising term bird head has been applied to individuals with a small head, large-appearing eyeballs, beaked nose, and underdeveloped chin. Such a physiognomy is not unique to any disease, but when combined with dwarfism it includes a few more or less specific syndromes. Up to 1976, approximately 25 cases had been reported, some with other skeletal and urogenital abnormalities, such as medial curvature of middle digits; occasional syndactyly of toes; dislocations of elbow, hip, and knee; premature closure of cranial sutures; and clubfoot deformity. These individuals are short at birth and remain so, living until adolescence or adulthood. Retardation is severe. A recessive autosomal type of inheritance is probable. At autopsy the brain is found to have a simplified convolutional pattern; one of our patients had a type of myelin degeneration similar to that of Pelizaeus-Merzbacher disease.

2. **Russell-Silver syndrome.** Possibly an autosomal dominant pattern of inheritance, with short stature of prenatal onset, craniofacial dysostosis, short arms, congenital hemihypertrophy (arm and leg on one side larger and longer), pseudohydrocephalic head (normal-sized cranium with small facial bones), abnormalities of genital development in one-third of cases, delay in closure of fontanelles and in epiphyseal maturation, elevation of urinary gonadotropins. Some cases appear to be due to a nonmutational modification of genes, which are nonetheless inherited (imprinting).

3. **Smith-Lemli-Opitz syndrome.** Autosomal recessive inheritance with microcephaly, broad nasal tip and antverted
nares, wide-set eyes, epicanthal folds, ptosis, small chin, low-set ears, enlarged alveolar maxillary ridge, cutaneous syndactyly, hypospadias in boys, short stature, subnormal neonatal activity, normal amino acids and serum immunoglobulins. Older survivors are bereft of language and para- paretic, with increased reflexes and Babinski signs. The hips are usually dislocated. The karyotype is normal. The brain is small but has not been fully examined. Two of our patients are sibling.

4. **Rubinstein-Taybi syndrome.** Microcephaly but no craniose-nosis, downward palpebral slant, heavy eyebrows, beaked nose with nasal septum extending below alae nasi, mild retrognotathia, “grimacing smile,” strabismus, cataracts, ob-struction of nasolacrimal canals, broad thumbs and toes, cli-nodactyly, overlapping digits, excessive hair growth, hypotonia, lax ligaments, stiff gait, seizures, hyperactive tendon reflexes, absence of corpus callosum, mental retardation, and short stature. This dominantly inherited disease is due to disrup-tion of so-called CREB-binding protein, a nuclear protein necessary for gene expression that is modulated by cyclic AMP.

5. **Pierre Robin syndrome.** Possible autosomal recessive pattern of inheritance with microcephaly but no craniosenosis, small and symmetrically receded chin, glossoptosis (tongue falls back into pharynx), cleft palate, flat bridge of nose, low-set ears, mental deficiency, and congenital heart disease in half the cases. Camptomelia (bent bones), diastrophic dwarfism (short limbs) common.

6. **De Lange syndrome (Cornelia DeLange syndrome).** The phenotype shows some degree of variability, but the essential diagnostic features are intrauterine growth retardation and stature falling below the third percentile at all ages, micro-brachycephaly, generalized hirsutism and eyebrows that meet across the midline (synophrys), anteverted nostrils, long upper lip, and skeletal abnormalities (flexion of elbows, web-bing of second and third toes, clinodactyly of fifth fingers, transverse palmar crease). All are moderately or, more often, severely retarded mentally, which, with craniofacial abnor-malities, is diagnostic. It has been said, and it has been our experience, that many of these patients are prone to have a bad disposition, manifest by biting and spitting. There are no chromosomal abnormalities. A polygenic inheritance has been postulated, but most cases are sporadic.

7. **Smith-Magenis syndrome.** This is due to deletions on chro-mosome 17, in which there is learning disability, severe behav-ioral problems (violence and self-injury), hyperactivity, deafness, and ocular abnormalities.

**Neurocutaneous Anomalies with Mental Retardation**

It is not surprising that skin and nervous system should share in pathologic states that impair development, since both have a com-mon ectodermal derivation. Nevertheless, it is difficult to find a common theme in the diseases that affect both organs. In some instances, it is clear that ectoderm has been malformed from early intrauterine life; in others, a number of nondevelopmental acquired diseases of skin may have been superimposed. For reasons to be elaborated later, neurofibromatosis, tuberous sclerosis, and Sturge-Weber encephalofacial angiomatosis must be set apart in a different category of disease termed phakomatoses.

Hemangiomas of the skin are without doubt the most frequent cutaneous abnormalities present at birth, and usually they are entirely innocent. Many recede in the first months of life. On the other hand, an extensive vascular nevus located in the territory of the trigeminal nerve—and sometimes in other parts of the body as well—causes permanent disfigurement and usually portends an associated cerebral lesion.

Other neurocutaneous diseases are summarized below. A more complete review of these diseases will be found in the article by Short and Adams in Fitzpatrick’s *Dermatology* and the monograph edited by Gomez, listed in the References. The related cat-egory of phakomatoses is discussed on page 865. The importance of recognizing the cutaneous abnormalities relates to the fact that the nervous system is usually abnormal, and often the skin lesion appears before the neurologic symptoms are detectable. Thus the skin lesion becomes a predictor of potential neurologic involve-ment.

1. **Basal-cell nevus syndrome.** This condition is transmitted as an autosomal dominant trait and is characterized by superfi-cial pits in the palms and soles; multiple solid or cystic tu-mors over the head, face, and neck appearing in infancy or early childhood; mental retardation in some cases; frontopari-etial bossing; hypertelorism; and kyphoscoliosis.

2. **Congenital ichthyosis, hypogonadism, and mental retardation.** This disorder is inherited as a sex-linked recessive trait. Aside from the characteristic triad of anomalies, there are no special features.

3. **Xeroderma pigmentosum.** The genetic pattern of inheritance is autosomal recessive. Skin lesions appear in infancy, taking the form of erythema, blistering, scaling, scarring, and pig-mentation on exposure to sunlight; old lesions are telangiec-tatic and parchment-like, covered with fine scales; skin cancer may develop later; loss of eyelashes, dry bulb conjunctivae; microcephaly, hypogonadism, and mental re-tardation (50 percent of cases). Kanda and associates classify this disease with the DeSanctis-Cacchione syndrome of “xerodermic idiocy” and believe the basic mechanism to be a faulty repair of DNA. These authors described two young adults with low intelligence, evidence of spinal cord degener-ation, and peripheral neuropathy. The peripheral nerve le-sions resembled those of amyloidosis, Riley-Day syndrome, and Fabry disease in that there was a predominant loss of small fibers. Other variants are described.

4. **Sjögren-Larssen syndrome.** Autosomal recessive with con-genital ichthyosiform erythroderma, normal or thin scalp hair, sometimes defective dental enamel, pigmentary degeneration of retinae, spastic legs, and mental retardation.

5. **Poikiloderma congenitale (Rothmund-Thompson syndrome).** Autosomal recessive heredity; appearance of skin changes from the third to sixth months of life; diffuse pink coloration of cheeks spreading to ears and buttocks, later replaced by macular and reticular pattern of skin atrophy mixed with striæ, telangiectasia, and pigmentation; sparse hair in half of the cases; cataracts; small genitalia; abnormal hands and feet; short stature; and mental retardation.

6. **Linear sebaceous nevus syndrome.** Genetics uncertain. Here there is a linear nevus of one side of face and trunk, lipoder-moids on bulbar conjunctivae, vascularization of corneas, mental retardation, focal seizures, and spike and slow waves in the EEG.
7. Incontinentia pigmenti (Bloch-Sulzberger syndrome). Only females affected; appearance of dermal lesions in first weeks of life; vesicles and bullae followed by hyperkeratoses and streaks of pigmentation, scarring of scalp, and alopecia; abnormalities of dentition; hemiparesis; quadriplegia; seizures; mental retardation; and up to 50 percent eosinophils in blood. The status of this disease is uncertain.

8. Focal dermal hypoplasia. Also a disease limited to females. Areas of dermal hypoplasia with protrusions of subcutaneous fat, hypo- and hyperpigmentation, scoliosis, syndactyly in a few, short stature, thin body habitus. Intelligence is occasionally subnormal.

Other rare entities are neurocutaneous melanosis, neuroectodermal melanolysosomal disease with mental retardation, progeria, Cockayne syndrome, and ataxia-telangiectasia (Chap. 37; see also Gomez 1987).

Dysraphism, or Rachischisis
(Encephalocoeles and Spina Bifida)

Included under this heading are the large number of disorders of fusion of dorsal midline structures of the primitive neural tube, a process that takes place during the first 3 weeks of postconceptual life. Exogenous factors are presumed to be operative in most cases. The entire cranium may be missing at birth, and the undeveloped brain lies in the base of the skull, a small vascular mass without recognizable nervous structures. This state, anencephaly, has been discussed earlier, under “Disturbances of Neuronal Migration,” and it is the most frequent of the rachischises. It has many associations with other conditions in which the vertebral laminae fail to fuse.

An evagination of brain tissue and its coverings through an unfused midline defect in the skull is called an encephalocele. Frontal encephalocoeles may deform the forehead or remain occult. Associated defects of the frontal cortex, anterior corpus callosum, and optic-hypothalamic structures as well as CSF leakage into frontal or ethmoid sinuses pose a risk of meningitis. Some of these children are relatively normal mentally. Far more severe are the posterior encephalocoeles, some of which are enormous and are attended by grave neurologic deficits. However, lesser degrees of the defect are well known and may be small or hidden, such as a meningoencephalocele connected with the rest of the brain through a small opening in the skull. Small nasal encephalocoeles may cause no neurologic signs, but if they are mistaken for nasal polyps and snipped off, CSF fistulae may result. The larger occipital ones are associated with blindness, ataxia, and mental retardation.

A failure of development of the midline portion of the cerebellum, referred to earlier, forms the basis of the Dandy-Walker syndrome (Fig. 38-2). A cyst-like structure, representing the greatly dilated fourth ventricle, expands in the midline, causing the occipital bone to bulge posteriorly and displace the tentorium and torcular upward. In addition, the cerebellar vermis is aplastic, the corpus callosum may be deficient or absent, and there is dilatation of the aqueduct as well as the third and lateral ventricles.

Even more frequent are abnormalities of closure of the vertebral arches. These take the form of a spina bifida occulta, meningocoele, and meningomyelocele of the lumbosacral or other regions.

Figure 38-2. Dandy-Walker syndrome. MRI showing agenesis of the midline cerebellum and large midline cyst, representing the greatly dilated fourth ventricle, which occupies almost the entire posterior fossa. A. Axial view. B. Sagittal view.
In spina bifida occulta, the cord remains inside the canal and there is no external sac, although a subcutaneous lipoma or a dimple or wisp of hair on the overlying skin may mark the site of the lesion. In meningocele, there is a protrusion of only the dura and arachnoid through the defect in the vertebral laminae, forming a cystic swelling usually in the lumbosacral region; the cord remains in the canal, however. In meningo(myelo)cele, which is 10 times as frequent as meningocele, the cord (more often the cauda equina) is extruded also and is closely applied to the fundus of the cystic swelling.

The incidence of spinal dysraphism (myeloschisis), like that of anencephaly, varies widely from one locale to another, and the disorder is more likely to occur in a second child if one child has already been affected (the incidence then rises from 1 per 1000 to 40 to 50 per 1000). Exogenous factors (e.g., potato blight in Ireland) have been implicated in the genesis of both myeloschisis and anencephaly. Folic acid, given before the 28th day of pregnancy, can be protective; vitamin A may also have slight protective benefit.

With anencephaly, the diagnosis can often be inferred from the presence of a-β-fetoprotein in the amniotic fluid (sampled at 15 to 16 weeks of pregnancy) and the deformity confirmed by ultrasound in utero, as mentioned earlier in this chapter. Blood contamination is a source of error in the fetoprotein test (Milunsky). Acetylcholinesterase immunoassay, done on amniotic fluid, is another reliable means of confirming the presence of neural tube defects. Some parents, on receiving this information, request abortion.

In the case of meningo(myelo)cele, the child is born with a large externalized lumbosacral sac covered by delicate, weeping skin. It may have ruptured in utero or during birth, but more often the covering is intact. There is severe dysfunction of the cauda equina roots or conus medullaris contained in the sac. Stroking of the sac may elicit involuntary movements of the legs. As a rule the legs are motionless; urine dribbles, keeping the patient constantly wet; there is no response to pinprick over the lumbosacral zones; and the tendon reflexes are absent. In contrast, craneocervical structures are normal unless a Chiari malformation is associated (see further on). Differences are noted in the neurologic picture depending on the level of the lesion. If it is entirely sacral, bladder and bowel sphincters are affected but legs escape; if lower lumbar and sacral, the buttocks, legs, and feet are more impaired than hip flexors and quadriceps; if upper lumbar, the feet and legs are sometimes spared and ankle reflexes retained, and there may be Babinski signs. The two dreaded complications of these severe spinal defects are meningitis and progressive hydrocephalus from a Chiari malformation, which is often associated (see below). The subject of neural tube defects has been reviewed by Botto and colleagues.

**Treatment** Opinions as to proper management vary considerably. Excision and closure of the coverings of the meningo(myelo)cele in the first few days of life is advised if the objective is to prevent a fatal meningitis. After a few weeks or months, as hydrocephalus reveals its presence by rapid increase in head size and enlargement of the ventricles on the CT scan, a ventriculoatrial or ventriculo-peritoneal shunt is required. Patients with high spinal lesions and total paraplegia, kyphosis, hydrocephalus, and other major congenital anomalies are usually not accepted for treatment. Less than 30 percent of such patients survive beyond 1 year, and the long-term results of treating these patients have not been encouraging. Lorber and others report that 80 to 90 percent of their surviving patients are mentally retarded to some degree and are paraplegic—thus totally dependent on others for their care. The decision to undertake rather formidable surgical procedures is being questioned more and more frequently. Exceptionally, the patient with meningomyelocele, and most of those with lumbar meningocele, are mentally normal. Clinical differentiation of this mental state is obviously important.

**Other Developmental Spinal Defects and Delayed Effects of Failure of Midline Fusion, Including Tethered Cord** The problems of meningomyelocele and its complications are so strictly pediatric and surgical that the neurologist seldom becomes involved—except perhaps in the initial evaluation of the patient—in the treatment of meningeal infection, or in the case of shunt failure with decapensation of hydrocephalus. Of greater interest to the neurologist are a series of closely related abnormalities that produce symptoms for the first time in late childhood, adolescence, or even adult life. These include sinus tracts with recurrent meningeal infections, lumbosacral lipomas with low tethering of the spinal cord (“tethered cord”), and a delayed radicular or spinal cord syndrome; diastematomyelia, cysts, or tumors with spina bifida and a progressive myeloradiculopathy; and a Chiari malformation and syringomyelia that first present in adolescence or adult life. These abnormalities are described below.

Another class of disorders involves an occult lumbosacral dysraphism that is not inherited but is due to faulty development of the cell mass that lies caudal to the posterior neuropore (normally this undergoes closure by the 28th day of embryonic life). Occult spinal dysraphism of this type is also associated with meningoceles, lipomas, and sacrococcygeal teratomas. Another well-recognized anomaly is agenesia of the sacrum and sometimes the lower lumbar vertebrae (caudal regression syndrome). Interestingly, in 15 percent of such cases, the mother is diabetic (Lyon and Evrard). Here there is flaccid paralysis of legs, often with arthrogrypotic contractions and urinary incontinence. Sensory loss is less prominent, mental function develops normally, and there is no hydrocephalus.

**Sinus tracts** in the lumbosacral or occipital regions are of importance, for they may be a source of bacterial meningitis at any age. They are often betrayed by a small dimple in the skin or by a tuft of hair along the posterior surface of the body in the midline. (The pilonidal sinus should not be included in this group.) The sinus tract may lead to a terminal meningocele and be associated with dermoid cysts or fibrolipomas in the central part of the tract. Cloacal defects (no abdominal wall and no partition between bladder and rectum) may be combined with anterior meningoceles. Evidence of sinus tracts should be sought in every instance of unexplained meningitis, especially when there has been recurrent infection or the cultured organism is of nosocomial dermal origin.

There are, in addition, other congenital cysts and tumors, particularly lipoma and dermoid, that arise in the filum terminale and attach (tether) the cord to the sacrum; progressive symptoms and signs are produced as the spine elongates during development, stretching the caudally fixed cord (Fig. 38-3). Some of these children have bladder and leg weakness soon after birth. Others deteriorate neurologically at a later age (generally between 2 and 16 years, sometimes later—see below). According to Chapman and Davis, it is not the myelolipoma but the tethering of the cord that gives rise to symptoms; removal of the tumor is of little benefit unless the cord is untethered (detached from the sacrum) at the same time. This may be difficult, for the lipoma may be fused with the dorsal surface of the spinal cord.

**Diastematomyelia** is another unusual abnormality of the spinal cord often associated with spina bifida. Here a bony spicule or
fibrous band protrudes into the spinal canal from the body of one of the thoracic or upper lumbar vertebrae and divides the spinal cord in two halves for a variable vertical extent. Or the division of the cord may be complete, each half with its own dural sac and complete set of nerve roots. This longitudinal fissuring and doubling of the cord are spoken of as diplomyelia. With body growth, it leads to a traction myelopathy, presenting with pain and progressive sensory, motor, and bladder symptoms, sometimes as late as adult life. Removal of the fibrous-bony spicule and untethering of the spinal cord have been beneficial in some cases.

Several clinical syndromes of delayed progressive disease (in adolescents or adults), due mainly to a tethered cord, have been delineated:

1. Progressive cauda equina syndrome with lesions in the lumbar-sacral region. In our experience this has been the most common presentation of the tethered cord syndrome, with or without a lipoma or dermoid. Complex disturbances of bladder function that produce urgency and incontinence beginning in the second or third decade may be the only manifestation, or the bladder symptoms may be combined with impotence (in the male) and numbness of the feet and legs or foot drop (Pang and Wilberger). Several of our adult patients have had unusual visceral reflex reactions, such as involun-

tary defecation or priapism with stimulation of the abdomen or perineum.

2. Progressive spastic weakness in some of the weak muscles of the legs in a patient known to have had a meningocele or meningomyelocele. Presumably the spinal cord, which is securely attached to the lumbar vertebrae, is stretched during the period of rapid lengthening of the vertebral column.

3. An acute cauda equina syndrome, following some unusual activity or accident (e.g., rowing or a fall in a sitting position), in patients who have had an asymptomatic or symptomatic spina bifida or meningocele. The implicated sensory and motor roots are believed to be injured by sudden or repeated stretching.

4. Syringomyelia (page 1082). This is a developmental cavity within the cervical cord, extending a variable distance caudally or rostrally, associated with an Arnold-Chiari malformation (see below). Also, there are a variety of neurologic problems associated with spinal abnormalities in the high cervical region [fusion of atlas and occiput or of cervical vertebrae (Klippel-Feil syndrome), congenital dislocation of the odontoid process and atlas, platybasia and basilar impression]. These abnormalities are reviewed in Chap. 44, with other diseases of the spinal cord.

Chiari Malformation

Encompassed by this term are a number of congenital anomalies at the base of the brain, the most consistent of which are (1) extension of a tongue of cerebellar tissue, posterior to the medulla and spinal cord, into the cervical canal and (2) displacement of the medulla into the cervical canal, along with the inferior part of the fourth ventricle. These and associated anomalies were first clearly described by Chiari (1891, 1896). Arnold’s name is often attached to the syndrome, but his contribution to our understanding of these malformations was relatively insignificant. Use of the double eponym Arnold-Chiari malformation is so entrenched that a dispute over its propriety will not alter its usage. Chiari recognized four types of abnormality. In recent years the term has come to be restricted to Chiari’s types I and II—i.e., to the cerebellomedullary malformation without and with a meningomyelocele, respectively. Type III Chiari malformation is no more than a high cervical or occipitocervical meningomyelocele with cerebellar herniation, and type IV consists only of cerebellar hypoplasia. It should be emphasized that a proportion of normal individuals have a small tongue of the posterior cerebellum protruding below the opening of the foramen magnum by a few millimeters; this is usually of no significance and does not justify inclusion as a Chiari malformation.

Several other morphologic features are characteristic of the true anomaly. The medulla and pons are elongated and the aqueduct is narrowed. The displaced tissue (medulla and cerebellum) occludes the foramen magnum; the remainder of the cerebellum, which is small, is also displaced so as to obliterate the cisterna magna. The foramina of Luschka and Magendie open into the cervical canal, and the arachnoidal tissue around the herniated brain-stem and cerebellum is fibrotic. All these factors are probably operative in the production of hydrocephalus, which is always associated. Just below the herniated tail of cerebellar tissue there is a kink or spur in the spinal cord, pushed posteriorly by the lower end of the fourth ventricle. In this type of malformation, a meningomyelocele is nearly always found. It should also be empha-
sized that hydromyelia or syringomyelia of the cervical cord are commonly associated findings.

Developmental abnormalities of the cerebrum (particularly polymicrogyria) may coexist, and the lower end of the spinal cord (i.e., filum terminale) may extend as low as the sacrum. There are usually cranial bony abnormalities as well. The posterior fossa is small; the foramen magnum is enlarged and grooved posteriorly. Nishikawa et al have suggested that smallness of the posterior fossa, with overcrowding, is the primary abnormality leading to the brain malformation. Often the base of the skull is flattened or indented by the cervical spine (basilar impression).

**Clinical Manifestations** In type II Chiari malformation (with meningocele or other signs of dysraphism), neurologic symptoms may not develop until adolescence or adult life. The symptoms may be those of (1) increased intracranial pressure, mainly headache, (2) progressive cerebellar ataxia, (3) progressive spastic quadriparesis, (4) downbeating nystagmus, or (5) cervical syringomyelia (segmental atrophy and sensory loss, with or without pain). Or the patient may show a combination of disorders of the lower cranial nerves, cerebellum, medulla, and spinal cord (sensory and motor tract disorders), usually in conjunction with headache that is mainly occipital. This combination of symptoms is often mistaken for multiple sclerosis or a foramen magnum tumor. The symptoms may have an acute onset after sustained extension of the neck, as, for example, after a long session of dental work, hairdressing in women, or chiropractic manipulation. The physical habitus of such patients may be normal, but about 25 percent have signs of an arrested hydrocephalus or a short “bull neck.” When basilar impression (a congenital abnormality of the occipital bone that invaginates the posterior atlas into the cranial cavity) and a Chiari malformation coexist, it may be impossible to decide which of the two is responsible for the clinical findings.

The tongue of cerebellar tissue and the kinked cervical cord obstruct the upward flow of dye and give a highly characteristic radiologic profile, particularly on sagittal MRI (Fig. 38-4). Inspection of the axial sections of CT scans at the level of the foramen magnum also demonstrates crowding of the upper cervical canal by inferiorly displaced cerebellar tissue, but one must be aware of the variations in the normal position of the cerebellar tonsils at this level. The low-pressure CSF syndrome may also lead to a slight descent of the cerebellar tonsils that is reversible and in our experience not indicative of a Chiari malformation. The CSF is usually normal but may show an elevated pressure and protein level in some cases.

**Treatment** The treatment of Chiari malformation (and basilar impression) is far from satisfactory. If clinical progression is slight or uncertain, it is probably best to do nothing. If progression is certain and disability is increasing, upper cervical laminectomy and enlargement of the foramen magnum are indicated. Often this procedure halts the progress of the neurologic illness, arrests the hydrocephalus, or results in some improvement. The outcome, in our experience, has been less satisfactory when decompression was performed mainly for intractable headache. The surgical procedure must be done cautiously. Opening of the dura and extensive manipulation of the malformation or excision of herniated cerebellum may aggravate the symptoms or even cause death. The treatment of an associated syringomyelia and other developmental abnormalities in this region is discussed further on page 1082. We are unable to comment on the use by a limited number of neurosurgeons of posterior fossa decompression for the treatment of chronic fatigue syndrome except to say that it is illogical, even when a Chiari malformation is detected.

---

**CHROMOSOMAL ABNORMALITIES (KARYOTYPIC CHROMOSOMAL DYSGENESES)**

A mid-twentieth-century discovery of outstanding significance was the recognition of a group of developmental anomalies of the brain and other organs associated with a demonstrable abnormality of the karyotype of autosomal and sex chromosomes. Jacobs and Lejeune almost simultaneously were the first to note a triplication of the 21st chromosome in the Down syndrome, and there followed the discovery of a number of other trisomies as well as deletions or translocations of other autosomal chromosomes and a lack or excess of one of the sex chromosomes. Such an event must take place
sometime after the formation of the oocyte, during the long period when it lies fallow in the ovary or during the process of conception or germination and first cell divisions. Thus, all the cells in the embryo may carry the changed chromosome or only some of them may, the latter condition being called mosaicism.

The precise manner in which triplication or some other imperfection of a chromosome is able to derail the pathways of ontogenesis is a mystery. In some instances, a chromosomal imperfection may result from the lack of a gene or a distortion or fragmentation of a gene, as in the fragile-X syndrome.

Certain chromosomal abnormalities are incompatible with life, and it has been found that the cells of many unexplained abortuses and stillborns show abnormal karyotypes. On the other hand, the organism may survive and exhibit any one of many syndromes, of which the following are the best known and most frequent: (1) Down syndrome (mongolism, trisomy 21); (2) one type of arrhinencephaly (trisomy 13, Patau syndrome); (3) trisomy 18 (Edwards syndrome); (4) cri-du-chat syndrome (deletion of short arm of chromosome 5); (5) monosomy 21 (so-called antimongolism); (6) ring chromosomes; (7) Klinefelter syndrome (XXY); (8) Turner syndrome (XO); (9) others (XXXX, XXX, XYY, YY, XXXY); (10) fragile X syndrome, the most common form of inherited retardation; (11) Williams syndrome; and (12) Prader-Willi and Angelman syndromes. There are other less frequent types, some of which are also discussed below. The overall frequency of chromosomal abnormalities in live births is 0.6 percent (see the review by Kalter and Warkany). For a comprehensive account of the chromosome-linked disorders the reader is referred to the article by Lemieux and for speculations on the nature of genetic retardations, to that of Nokelainen and Flint.

**Down Syndrome** Described first in 1866 by Langdon Down, this is the best known of the chromosomal dysgeneses. The frequency is 1 in 600 to 700 births, and this condition accounts for approximately 10 percent of all cases in every large series of cases of severe mental retardation. Familiarity with the condition permits its recognition at birth, but it becomes more obvious with advancing age. The round head, open mouth, stubby hands, slanting palpebral fissures, and short stature impart an unmistakable appearance. The ears are low-set and oval, with small lobules. The palpebral fissures slant slightly upward and outward owing to the presence of medial epicanthal folds that partly cover the inner canthi (hence the old term mongolism). The bridge of the nose is poorly developed and the face is flattened (hypoplasia of the maxillae). The tongue is usually enlarged, heavily fissured, and protruded. Gray-white specks of depigmentation are seen in the irides (Brushfield spots). The little fingers are often short (hypoplastic middle phalanx) and incurved (clinodactyly). The fontanels are patent and slow to close. The hands are broad, with a single transverse (simian) palmar crease and other characteristic dermal markings. Lenticular opacities and congenital heart lesions (septal and other defects) as well as gastrointestinal abnormalities (stenosis of duodenum) are frequent. The patient with Down syndrome is slightly below average size at birth and is characteristically of short stature at later periods of life. The height attained in adult life seldom exceeds that of a 10-year-old child.

Hyponxia of limbs is a prominent finding. At first the Moro response is reduced or absent, and feeding is difficult. Most affected children do not walk until 3 to 4 years of age; their acquisition of speech is delayed, but over 90 percent talk by 5 years. The intelligence quotient (IQ) is variable, and that of a large group follows a Gaussian curve with the median IQ being 40 to 50 and the range, 20 to 70. A placid, docile, and affectionate personality characterizes most Down patients. A high incidence of atlantoaxial instability puts these individuals at risk of traumatic spinal cord compression in athletic activities. Also, an increased incidence of myelocytic and lymphocytic leukemia takes its toll. A number of patients have had embolic strokes and brain abscesses secondary to cardiac abnormalities. There is disproportionate occurrence of the rare cerebrovascular disorder known as moyamoya (page 706). Life expectancy is later shortened by the almost universal development of Alzheimer disease by the 40th year of life. This is explained by the presence of the gene for the precursor of the protein amyloid, a central factor in the development of Alzheimer disease, on the triplicated chromosome 21.

One cannot distinguish the Down syndrome with the more common triplication of chromosome 21 from that due to a translocation. There is a strong correlation between some of these types and the age of the mother. The triplication is found in the offspring of older mothers, whereas the less frequent translocation is found equally in the offspring of young and old. In other subtypes of the Down syndrome, referred to as mosaics, some cells share in the chromosomal abnormality and others are normal. Mosaics have atypical forms of the syndrome, and some such individuals are actually of normal intelligence. Laboratory tests are not helpful in clarifying the mechanism of the disorder.

The genetic changes that lead to cerebral maldevelopment and dysmorphic physical features are just beginning to be understood. A connection to genes that code for enzymes of folate has been suggested (among other mechanisms). The genetic aspects, as well as features pertaining to the medical care of these patients, are summarized by Rotzen and Patterson. They emphasize the high frequency of enteric sprue (celiac disease) and hypothyroidism and the need for screening for these conditions.

**Pathologic Findings** Brain weight is approximately 10 percent less than average. The convolutional pattern is rather simple. The frontal lobes are smaller than normal, and the superior temporal gyri are thin. There are claims of delayed myelination of cerebral white matter and also of immature and poorly differentiated cortical neurons. Alzheimer neurofibrillary changes and neuritic plaques are practically always found in Down cases beyond 40 years of age. As Alzheimer disease develops, the usual clinical picture is marked by inattentiveness, reduced speech, impairment of visuospatial orientation, loss of memory and judgment, and seizures.

It is possible to make the diagnosis of Down syndrome by demonstrating the chromosomal abnormalities in cells of the amniotic fluid. About one-third of pregnant mothers also have an abnormal elevation of serum α-fetoprotein in the second trimester of pregnancy. Other independent predictors of fetal Down syndrome are elevated serum chorionic gonadotropin and decreased estriol (Haddow et al). One can uncover a considerable proportion of the Down population by prenatal screening for these serum markers and by performing amniocentesis on women with positive tests to search for the chromosomal abnormality. Early detection is aided by the absence on imaging of a nasal bone between 11 and 14 weeks, at which time it is normally detected (Cicero et al).

**Other Chromosomal Dysgeneses**

These are listed again here with brief descriptions of their main features.
1. **Trisomy 13 (Patau syndrome).** Frequency 1 in 2000 live births, more female than male, average maternal age 31 years, microcephaly and sloping forehead, microphthalmos, coloboma of iris, corneal opacities, anosmia, low-set ears, cleft lip and palate, capillary hemangiomata, polydactyly, flexed fingers, posterior prominence of heels, dextrocardia, umbilical hernia, impaired hearing, hypertonia, severe mental retardation, death in early childhood.

2. **Trisomy 18.** Frequency 1 in 4000 live births, more in females, average maternal age 34 years, slow growth, occasional seizures, severe mental retardation, hypertonia, ptosis and lid abnormalities, low-set ears, small mouth, mottled skin, clenched fists with index fingers overlapping the third finger, syndactyly, rocker-bottom feet, shortened big toe, ventricular septal defect, umbilical and inguinal hernias, short sternum, small pelvis, small mandible, death in early infancy.

3. **Cri-du-chat syndrome (deletion in short arm of chromosome 5).** Abnormal cry, like a kitten, severe mental retardation, hypertelorism, epicanthal folds, brachycephaly, moon face, antimongoloid slant of palpebral fissures, micrognathia, hypotonia, strabismus.

4. **Ring chromosomes.** Mental retardation with variable physical abnormalities.

5. **Klinefelter syndrome (XXY).** Only males. Eunuchoid appearance, wide arm span, sparse facial and body hair, high-pitched voice, gynecomastia, small testicles, usually mentally retarded but not severely so; high incidence of psychosis, asthma, and diabetes.

6. **Turner syndrome (XO).** Only females. Triangular face, small chin, occasionally hypertelorism and epicanthal folds, widely spaced nipples, clinodactyly, cubitus valgus, hypoplastic nails, short stature, webbed neck, delayed sexual development, mild mental retardation.

7. **Colpocephaly.** A rare type of malformation of the brain consisting of marked dilatation of the occipital horns of the lateral ventricles, thickening of the overlying rim of cortical gray matter, and thinning of the white matter. The associated clinical picture comprises mental retardation, spasticity, seizures, and visual abnormalities (due to optic nerve hypoplasia). This disorder is probably of diverse causation, but it is listed here with the chromosomal abnormalities because some cases have been associated with the mosaicism for trisomy 8 (Herskowitz et al). The term *colpocephaly* is often used incorrectly to apply to all forms of ventricular enlargement (including hydrocephalus) associated with abnormal development of the brain.

8. **Fragile X syndrome (see page 887 for clinical details).** This abnormality is among the most common inherited form of mental retardation, estimated to occur in 1 of every 1500 male births and accounting for 10 percent of severe mental retardation in males. Females, with two X chromosomes, are affected about half as frequently, and then only to a slight degree. With the advent of new markers for the detailed structure of chromosomes, Lubs observed an unusual site of frequent breakage (“fragility”) on the X chromosome and related it to a syndrome that includes mental retardation, flaring ears, elongated facies, slightly reduced cranial perimeter, normal stature, and enlarged testes. A rare progressive ataxia has been reported in adults who harbor the chromosomal abnormality.

   The chromosomal fragility appears to be due to a heritable, unstable CGG repeating sequence in the X-chromosome. Affected individuals have over 230 repeats and carriers have 60 to 230 repeats. The prolonged sequence inactivates a gene (FMR1) that codes for an RNA-binding protein of as yet an unknown connection to brain function. The genetics of this and other retardations is extensively reviewed by Nokelainen and Flint. Rousseau and colleagues have described a simple and sensitive test, using DNA analysis, for the diagnosis of the syndrome both prenatally and after birth. Because of mosaicism, the length of the triplet repeat does not directly relate to the degree of expression of retardation, and the fragile X alteration occasionally turns up in mentally normal males; in some instances the male children of their daughters have the disease. In some of our cases, the intellectual deficit has been mild in degree; and the main abnormalities have taken the form of troublesome behavior, logorrhea, an autistic type of gaze aversion, and asociality. These and other peculiar features of the syndrome and its unique pattern of inheritance (it is neither recessive nor dominant) have been discussed by Shapiro.

9. **Williams syndrome.** Described by J. C. P. Williams of Australia from the perspective of a supra-valvular aortic stenosis and later by Beuren and colleagues, this unique combination of cerebral maldevelopment and cardiovascular abnormalities has been traced in most patients to a microdeletion on chromosome 7 in the region of the gene that codes for the protein elastin. Its frequency is 1 in 20,000 newborns. Further discussion of clinical features of this syndrome will be found on page 888.

10. **Prader-Willi and Angelman syndromes.** The Prader-Willi syndrome has already been mentioned in relation to the hyperphagia of hypothalamic disorders (page 486). It is not uncommon (1 in 20,000 births) and affects both sexes equally. Hypotonia (floppy infant), areflexia, small stature, dysmorphic facies, and hypoplastic genitalia are evident, and arthrogryposis may be present at birth. After the first year, mental retardation becomes obvious and obesity, due to hyperphagia, becomes prominent. Patients are identified by the “H3O” mnemonic, referring to hypomnesia, hypotonia, hypogonadism, and obesity. The disorder is associated with a deletion at 15q11-q13 (a so-called microdeletion, as in Williams syndrome), which can be identified by a combination of cytogenetic and DNA analyses. In 70 percent of cases the disease is due to a noninherited deletion from the paternal X chromosome.

   The Angelman syndrome, another cause of severe mental retardation, is associated with the identical chromosomal abnormality to that found in the Prader-Willi syndrome, but there is usually a maternally inherited single gene defect. The difference in phenotype derives from a complex genetic phenomenon termed spatially restricted imprinting. The phenotype comprises severe mental retardation, microcephaly, refractory seizures, absence of speech, ataxia, inappropriate laughter, prominent jaw, thin upper lip, and prolonged tongue. Outstanding are an unusual marionette-like stance coupled with a persistent tendency to
laugh and smile (hence the old name “happy puppet syndrome”) (see also Chap. 37).

11. Rett syndrome, discussed more fully on page 888, is mentioned here because it is due to a dominant defect on the X chromosome. It affects 1 of every 10,000 to 15,000 girls. After 6 to 18 months of normal development, motor skills and mental abilities seem slowly to regress. Certain hand-wringing and other stereotyped hand movements appear as the disease progresses and are characteristic.

Several generalizations can be made about these chromosomal dysgeneses. First, the autosomal ones are often lethal (Rett syndrome is an exception), and they almost always have a devastating effect on cerebral growth and development, whether the infant survives or not. Anomalies of nonneural structures are regularly present—an association so constant that one may safely predict that a normally formed infant will not have a detectable chromosomal defect. However, only in the Down syndrome and trisomy 13 (and possibly trisomy 18) are the physiognomy and bodily configuration highly characteristic. Surprisingly, some of the most grotesque disfigurements, such as anencephaly and multiple severe congenital anomalies, are not related to a morphologic abnormality of chromosomes. By contrast, an insufficiency of sex chromosomes induces only subtle effects on the brain, affecting intellect and personality; to some extent this is true of supernumerary sex chromosomes (XYY, for example).

The nature of the basic abnormality of the brain underlying the mental retardation in many of these chromosomal dysgeneses has not been ascertained. The cerebra are slightly small, but only minor changes are seen in the convolutional pattern and cortical architecture in conventional microscopic preparations. Neurocellular methodologies are not sufficiently advanced to reveal the fundamental cerebral abnormality.

Teratologic Factors

A number of observations have repudiated the former belief that the human embryo is naturally shielded against exogenous causes of maldevelopment. Irradiation during the first trimester, rubella and CMV infections, severe hypothyroidism of the mother during this same period, and the action of aminopterin, alcohol, vitamin A, and thalidomide have all been observed to give rise to serious disorders of development. Also, the offsping of mothers receiving anticonvulsant drugs during the early months of pregnancy have a slightly increased risk of developing birth defects (approximately 5 percent, compared to 3 percent for the general population—see page 296). Among anticonvulsants, the greatest risk is with trimethadione, now rarely used; but phenytoin, carbamazepine, valproate, and phenobarbital have also been implicated. Cleft lip and palate are the most common anomalies attributable to anticonvulsant drugs; other craniofacial defects, spina bifida, minor cardiac defects, and dysraphisms have also been reported at a slightly increased rate (Janz et al). Concerning this, and even more so for other teratogens, there is much controversy. Claims and counterclaims have been made concerning the pathogenicity of numerous substances. Mainly, the data are from animals given amounts far in excess of any possible therapeutic doses in humans. The data from humans are so meager that they are not discussed here. The reader should refer to the article by Kalter and Warkany for further information.

THE PHAKOMATOSES
(CONGENITAL NEUROECTODERMOSSES)

As stated earlier, there are two broad categories of neurocutaneous diseases. In one, the infant is born with a special type of skin disease or develops it in the first weeks of life; in the other, particular forms of cutaneous abnormality, though often present in minor degree at birth, later evolve as quasineoplastic disorders. The latter, to which van der Hoeve (1920) applied the term phakomatoses (from the Greek phakos, meaning “mother spot,” “mole,” or “freckle”), include tuberous sclerosis, neurofibromatosis, and cutaneous angiomasosis with CNS abnormalities. These diseases have many features in common—hereditary transmission, involvement of organs of ectodermal origin (nervous system, eyeball, retina, and skin), slow evolution of lesions in childhood and adolescence, tendency to form hamartomas (benign tumor-like formations due to maldevelopment), and a disposition to fatal malignant transformation. These disorders are discussed below and listed in Table 38-4.

Tuberous Sclerosis (Bourneville Disease)

Tuberous sclerosis is a congenital disease of hereditary type in which a variety of lesions, due to a limited hyperplasia of ectodermal and mesodermal cells, appear in the skin, nervous system, heart, kidney, and other organs. It is characterized clinically by the triad of adenoma sebaceum, epilepsy, and mental retardation. Hypomelanotic skin macules (“ash-leaf” lesions) are another-constant feature; the subependimal fibrotic “shagreen patch” is diagnostic.

It is stated that Virchow recognized scleromas of the cerebrum in the 1860s and that von Recklinghausen reported a similar lesion combined with multiple myomata of the heart in 1862, but Bourneville’s articles, appearing between 1880 and 1900, presented the first systematic accounts of the disease, and it was he who related the cerebral lesions to those of the skin of the face. Vogt (1890) fully appreciated the significance of the neurocutaneous relationship and formally delineated the triad of facial adenoma sebaceum, epilepsy, and mental retardation. “Epiloga,” a term for the disease introduced by Sherlock in 1911, never gained general acceptance. These and other historical aspects are reviewed in Gomez’s monograph.

Epidemiology This disease has been described in all parts of the world and is equally frequent in all races and both sexes. Heredity is evident in only a minority of cases—50 percent in some series and as little as 14 percent in the series of Bundag and Evans (cited by Brett). The disease is determined by two autosomal dominant genes (see below). The estimated prevalence is 1 in 20,000 to 300,000. The disease involves many organs in addition to the skin and brain, and it may assume a diversity of forms, the least severe of which (i.e., the forme fruste) is difficult to diagnose; hence, one cannot be precise about its incidence. Tuberous sclerosis accounts for about 0.66 percent of the mentally retarded in institutions and 0.32 percent of epileptics. It is likely that data drawn from mental hospital populations have exaggerated the overall frequency of mental retardation (Gomez). The medical literature contains a number of reports of patients whose mentality is preserved and who have never had convulsions.

Etiology and Pathogenesis The disease is inherited in an autosomal dominant fashion. The abnormal gene is localized to one of two sites—the long arm of chromosome 9, designated as TSC 1 (hamartin), and the short arm of chromosome 16, TSC 2 (tuberlin). Hamartin and tuberin interact to suppress cell growth and function as tumor suppressor proteins. In tuberous sclerosis they are inactivated by mutations. This may, in part, explain the proclivity to develop various growths and hamartomas. The cerebral lesions and two of the three associated skin lesions of tuberous sclerosis are of this type. Several hypotheses relating to neuronal migration or to excessive secretion of growth factors have been proposed to link the inactivation of these genes with the pathogenesis of the characteristic lesions. The cellular elements within the nodular cerebral lesions (called tubers; see below) are abnormal in number, size, and orientation. The tumor-like growths in different organs may include cells of more than one type (e.g., fibroblasts, cardiac myoblasts, angioblasts, glioblasts, and neuroblasts), and their number is locally excessive. Something appears to have gone awry with the proliferative process during embryologic development, yet it is usually kept under control, in the sense that only rarely do the growths undergo malignant transformation. Highly specialized cells within the lesions may attain giant size; neurons three to four times normal size may be observed in the cerebral sclerosis. These facts emphasize the potentially blastomatous character of the process.

Clinical Manifestations The disease may be evident at the time of birth (the diagnosis has been made by CT scan in neonates), but more often the infant is judged at first to be normal. In approximately 75 percent of cases, attention is drawn to the disease initially by the occurrence of focal or generalized seizures or by retarded psychomotor development. As with any condition that leads to mental retardation, the first suspicion is raised by delay in reaching normal maturational milestones. Whatever the initial symptom, the convulsive disorder and mental retardation become more prominent within 2 to 3 years. The facial cutaneous abnormality, adenoma sebaceum, appears later in childhood, usually between the fourth and tenth years, and is progressive thereafter.

As the years pass, the seizures change pattern. In the first year or two they take the form of massive flexion spasms with hypersarrhythmia (irregular dysrhythmic bursts of high-voltage spikes and slow waves in the EEG). As many as 25 percent of our patients with these types of seizures have been found to have tuberous sclerosis. Later, the seizures change to more typical generalized motor and psychomotor attacks or atypical petit mal. Any one of the seizure types may be brief, especially if the patient is receiving anticonvulsant medication. Seizures are always the most reliable index of the cerebral lesions; focal neurologic abnormalities, which one might expect to occur from the size and location of the lesions, are distinctly uncommon.

Mental function continues to deteriorate slowly. Exceptionally there is a spastic weakness or mild choreoathetosis of the limbs and in a few cases an obstructive hydrocephalus. As in any state of severe mental retardation, a variety of nonspecific motor peculiarities—such as constant crying, muttering, stereotypical rocking and swaying movements, and digital mannerisms—may be observed. In nearly half of the cases, affective and behavioral disturbances, often of hyperkinetic and aggressive type, are added to the intellectual deficiency.

The lack of parallelism in the severity of the epilepsy, the mental deficit, and cutaneous abnormalities has been noted by all clinicians who have wide experience with this disease. Some patients are subject to recurrent seizures while retaining relatively normal mental function; in others, trivial skin lesions or a retinal phakoma may suggest the diagnosis in a mentally normal person with few seizures. In such cases, recognition may elude competent neurologists and dermatologists. As a general rule, early onset of seizures is predictive of mental retardation. Gomez and colleagues have suggested that the seizures damage the brain, a point with which we tend to agree in part. However, it seems likely that both the epilepsy and mental retardation are the product of severe involvement of the brain by the lesions of tuberous sclerosis.

Limitation of space allows no more than a catalogue of other visceral abnormalities. In about half the cases, gray or yellow plaques (in reality gliomatous tumors) may be found in the retina in or near the optic disc or at a distance from it. It is from this lesion, called a phakoma, that van der Hoeve derived the term that is applied to all neurocutaneous diseases of this class. About half of all benign rhabdomyomas of the heart are associated with tuberous sclerosis; if located in the wall of the atrium, they may cause conduction defects. Other benign tumors of mixed cell type (angiomylipomas) have been found in the kidneys, liver, lungs, thyroid, testes, and gastrointestinal tract. Cysts of the pleura or lungs, bone cysts in digits, and zones of marbling or densification in bones are some of the less common abnormalities.

In approximately 90 percent of patients with tuberous sclerosis, congenital hypomelanotic macules—“ash-leaf” lesions—formerly mistaken for partial albinism or vitiligo, appear before any of the other skin lesions (Fitzpatrick et al). Gold and Freeman as well as Fitzpatrick and colleagues have emphasized the frequency of these leukodermic lesions and their value in the diagnosis of tuberous sclerosis during infancy, before the appearance of the other characteristic cutaneous lesions. The hypomelanotic areas are arranged in linear fashion over the trunk or limbs and range in size from a few millimeters to several centimeters; their configuration is oval, with one end round and the other pointed, in the shape of an ash leaf. A Wood’s lamp, which transmits only ultraviolet rays, facilitates the demonstration of the ash-leaf lesions because of the absence of melanoblasts, which normally absorb light in the ultraviolet range (360-nm wavelength). These lesions become pink when rubbed and contain sweat glands; they are not usually present on the face or head. There is occasionally a white tuft of hair (poliosis). Electron microscopic examination of the hypomelanotic lesions shows a normal or reduced number of melanosomes, but their dopa reaction is reduced and melanosomes are small.
The well-developed facial lesions (adenomas of Pringle), pathognomonic of tuberous sclerosis, are present in 90 percent of patients over 4 years of age. Typically they are red to pink nodules with a smooth, glistening surface, and they tend to be limited to the nasolabial folds, cheeks, and chin; sometimes they also involve the forehead and scalp. Although called “adenoma sebaceum,” these nodules are actually angiofibromas; the sebaceous glands are only passively involved (Fig. 38-5). The earliest manifestation of facial angiofibromatosis may be a mild erythema over the cheeks and forehead, intensified by crying. The occurrence of large plaques of connective tissue on the forehead is usually expressive of a severe form of the disease.

On the trunk, the diagnostic lesion is the “shagreen patch” (in reality a plaque of subepidermal fibrosis) found most often in the lumbosacral region. It appears as a flat, slightly elevated, flesh-colored area of skin 1 to 10 cm in diameter, with a “pigskin,” “elephant hide,” or “orange peel” appearance (Fig. 38-6). Another common site of fibromatous involvement is the nail bed; subungual fibromas usually appear at puberty and continue to develop with age. Other common skin changes, not in themselves diagnostic, include fibroepithelial tags (soft fibromas), café au lait spots, and port-wine hemangiomas.

**Pathology**  
The brain exhibits a number of diagnostic anomalies. Broadening, unnatural whiteness, and firmness of parts of some of the cerebral convolutions are simulated by no other disease. These are the *tubers* after which the disease is named. On the surface of the brain, they range in width from 5 mm to 2 or 3 cm. Their cut surface reveals a lack of demarcation from cortex and white matter and the presence of white flecks of calcium; these, which are readily seen on CT scans and MRI, are called brain stones (see below and Fig. 38-7). The walls of the lateral ventricles may be encrusted with white or pink-white masses resembling candle gutterings. When calcified, they appear in radiographs as curvilinear opacities that follow the outline of the ventricle. Rarely, nodules of abnormal tissue are observed in the basal ganglia, thalamus, cerebellum, brainstem, and spinal cord.

Under the microscope the tubers are seen to be composed of interlacing rows of plump, fibrous astrocytes (much like an astrocytoma, though lacking in glial fibrillary protein). In the cerebral cortex and ganglionic structures, derangements of architecture result from the presence of abnormal-appearing cells: greatly enlarged “monstrous,” or “balloon” neurons and glial cells—often difficult to distinguish from one another. Also, displaced normal-sized neurons contribute to the chaotic histologic appearance. Gliomatous deposits may obstruct the foramina of Monro or the aqueduct or floor of the fourth ventricle, causing hydrocephalus. Neoplastic transformation of abnormal glial cells, a not infrequent occurrence, usually takes the form of a large-cell astrocytoma, less often of a glioblastoma or meningioma. Recently, certain relationships have been drawn between the balloon cells of this disease and similar cells in focal cortical dysplasias (see Crino for details).

The phakomas of the retina are also composed mainly of neuronal and glial components, but occasionally there is an admixture of fibrous tissue.

**Diagnosis**  
When the full combination of seizures and mental and dermal abnormalities is conjoined, the diagnosis is self-evident. It is the early stage of the disease and the *formes frustes* that give trouble, and here the experienced dermatologist can be of great help. Epilepsy—i.e., flexion spasms in infancy—and delay in psychomotor development are by no means diagnostic of tuberous sclerosis, since they occur in many diseases. It is in these cases and also in every sizable population of the epileptic or mentally retarded, especially when the family history is unrevealing, that a search for the dermal equivalents of the disease—the hypomelanic ash-leaf spots, adenoma sebaceum, collagenous skin patch, phakoma of the retina, or subungual or gingival fibromas—is so rewarding. The finding of any one of these lesions provides confirmation of the partial and atypical case. Adenoma sebaceum may occasionally occur alone and is easily confused with acne vulgaris in the adolescent. The history of epilepsy and/or the demonstration of a dull mentality are helpful, but neither is a requisite for the diagnosis of tuberous sclerosis (see the monograph by Gomez).

The most useful laboratory measures for corroborating the disease are the CT scan and MRI (Fig. 38-7). The calcific lesions tend to be periventricular and are particularly well shown on the CT scan, whereas MRI is more sensitive in detecting hamartomatous subcortical lesions. There is an absence of edema in the surrounding tissue. Roach and colleagues have indicated that an increasing number of cortical lesions demonstrated with MRI appears to correlate with an increased impairment of neurologic function.
Treatment Nothing can be offered in the way of prevention other than genetic counseling. Anticonvulsant therapy of the standard type suppresses the convulsive tendency more or less effectively and should be applied assiduously. Adrenocorticotropic hormone (ACTH) suppresses the flexor spasms in infancy and tends to normalize the EEG abnormality. It is pointless to attempt the excision of tumors, especially in severely affected individuals (with the exception of renal hamartomas that impair kidney function). However, there are patients who are not mentally impaired and who undergo dermabrasion of the facial lesions for cosmetic reasons, with the knowledge that these slowly regrow. To an increasing degree, neurosurgeons are excising single epileptogenic cortical tubers in otherwise relatively normal children.

Course and Prognosis In general, the disease advances so slowly that years must elapse before one can be sure of progression. Of the severe cases, approximately 30 percent die before the fifth year, and 50 to 75 percent before attaining adult age. Worsening is mainly in the mental sphere. Status epilepticus accounted for many deaths in the past, but improved anticonvulsant therapy has reduced this hazard. Neoplasias take their toll; the authors have had several such patients who died of malignant gliomas arising in striatohalamic regions.

Neurofibromatosis of von Recklinghausen

Neurofibromatosis (NF) is a comparatively common hereditary disease in which the skin, nervous system, bones, endocrine glands, and sometimes other organs are the sites of a variety of congenital abnormalities, often taking the form of benign tumors. The typical clinical picture, usually identifiable at a glance, consists of multiple circumscribed areas of increased skin pigmentation accompanied by dermal and neural tumors of various types.

The condition known as multiple idiopathic neuromas was the subject of a monograph by R. W. Smith in 1849; even at that time, he referred to examples recorded by other writers. It was von Recklinghausen, however, who in 1882 gave the definitive account of its clinical and pathologic features. The subsequent studies of the disease by Yakovlev and Guthrie, Lichtenstein, Ricardi, and Martuza and Eldridge, and more recently by Créange et al, and the comprehensive monographs of Crowe and Ricardi and their colleagues are informative references that provide a complete analysis of the clinical, pathologic, and genetic data pertaining to the disease.

Epidemiology Crowe and associates have calculated the prevalence of the disease to be 30 to 40 per 100,000, with the expectancy of one case in every 2500 to 3300 births. Approximately half of their cases had affected relatives, and in all instances the distribution of cases within a family was consistent with an autosomal dominant mode of inheritance. The disease has been observed in all races in different parts of the world, and males and females are about equally affected.

Cause and Pathogenesis The hereditary nature of NF has been appreciated for many years. More recently it has been established that NF comprises two distinct disorders, the genes for which are located on different chromosomes. Both are inherited in an autosomal dominant pattern with a high degree of penetrance, but half the cases are due to new mutations. The classic form of the disease with multiple neurofibromas, described below, is caused by a mutation located near the centromere on chromosome 17 in a gene called neurofibromin (Barker et al). The second type, in which the main feature is bilateral acoustic nerve neuromas, described further on, is caused by a gene termed merlin (also called schwannomin).

These two forms of NF have been loosely referred to as peripheral and central, respectively, but the terms neurofibromatosis type 1 (NF1) and neurofibromatosis type 2 (NF2) are less confusing (Martuza and Eldridge) and are used in the following discussion.

The pathogenesis is less obscure now that the genes implicated in both diseases have been identified. Both involve tumor suppres-
sion. As with tuberous sclerosis, there is a suggestion of a disorder that allows low-grade ectodermal cell proliferation without tumor transformation. Cellular elements derived from the neural crest (i.e., Schwann cells, melanocytes, and endoneurial fibroblasts, the natural components of skin and nerves) proliferate excessively in multiple foci, and the melanocytes function abnormally. The hormones and growth factors involved in this proliferative process and the mechanism by which it occurs are as obscure as in tuberous sclerosis.

**Neurofibromatosis Type 1 (Classic or Peripheral NF)** In the majority of patients, spots of hyperpigmentation and cutaneous and subcutaneous neurofibromatous tumors are the basis of clinical diagnosis. Pigmentary changes in the skin are nearly always present at birth, but neurofibromas are infrequent at that age. Both lesions increase in number and size during late childhood and adolescence. There may be a spurt of new lesions at puberty or during pregnancy. Exceptionally, a neurofibroma of a cranial nerve or a spinal root (sometimes with compression of the cord), disclosed during neurosurgical intervention, may be the initial manifestation of the disease. In the study of a large series of patients with neurofibromatosis (Crowe et al), approximately one-third were found to have only the cutaneous manifestations noted while being examined for symptoms of some other disease; that is to say, the NF was asymptomatic. Usually these are the patients with the slightest degree of cutaneous abnormality. Of the remaining two-thirds, most consulted a physician because of an embarrassing disfigurement produced by the skin tumors or because some of the neurofibromas were producing neurologic symptoms.

The patches of cutaneous pigmentation, appearing shortly after birth and occurring anywhere on the body, constitute the most obvious clinical expression of the disease. They are approximately oval in shape and vary in size from a millimeter or two to many centimeters and in color from a light to dark brown (the term *café au lait* is applied) and are rarely associated with any other pathologic state (Fig. 38-8). They do not appear to change in number as the patient ages, but they do enlarge during puberty and become more pigmented. In a survey of pigmented spots in the skin, Crowe and associates found that 10 percent of the normal population had one or more spots of this type; however, anyone with more than six such spots, some exceeding 1.5 cm in diameter in postpubertal individuals (bigger than 0.5 mm in prepubertal ones), nearly always proved to have von Recklinghausen disease. Of their 223 patients with NF, 95 percent had at least one spot and 78 percent had more than six large ones. Freckle-like or diffuse pigmentation of the axillae and other intertriginous areas (groin, under breast) and small, round, whitish spots are characteristic; when coupled with *café au lait* patches, they are virtually pathognomonic of the disease.

The appearance of multiple cutaneous and subcutaneous tumors in late childhood or early adolescence is the other principal feature of the disease. The cutaneous tumors are situated in the dermis and form discrete soft or firm papules varying in size from a few millimeters to a centimeter or more (molluscum fibrosum; Fig. 38-9). They assume many shapes—flattened, sessile, pedunculated, conical, lobulated, and so on. They are flesh-colored or violaceous and often topped with a comedo. When pressed, the soft tumors tend to invaginate through a small opening in the skin, giving the feeling of a seedless raisin or a scrotum without a testicle. This phenomenon, spoken of as “buttonholing,” is useful in distinguishing the lesions of this disease from other skin tumors,
accompanying hyperpigmentation overlies a plexiform neurofibroma and extends to the midline, one should suspect an intraspinal tumor at that level.

Another unique finding is the Lisch nodule. This is a small whitish spot (actually a hamartoma) in the iris that was present in 94 percent of Riccardi’s type 1 cases but was not found in patients with type 2 NF or in normal individuals (see Fig. 38-10 and below).

Headache, hydrocephalus, and tumors involving the optic pathways, meningiomas, gliomas, and malignant peripheral nerve tumors are common, even among adults, according to the survey of 158 patients by Créange and colleagues; also, pain was a common symptom in adults and often related to a malignant peripheral nerve sheath tumor.

Other abnormalities associated less consistently with type 1 (peripheral) NF include bone cysts, pathologic fractures (pseudarthrosis), cranial bone defects with pulsating exophthalmos (sphenoid bone dysgenesis), bone hypertrophy, precocious puberty, pheochromocytoma, scoliosis, syringomyelia, nodules of abnormal glial cells in brain and spinal cord, and macrocephaly, rarely with obstructive hydrocephalus due to overgrowth of glial tissue around the sylvian aqueduct and fourth ventricle. Some degree of intellectual impairment is common; it was found in 40 percent of Riccardi’s series of 133 patients. But in our experience the figure is much less and the impairment is usually not profound. Learning difficulty, developmental disorder, and hyperactivity have been more frequent abnormalities, occurring in almost 40 percent of patients. Rosman and Pearce have ascribed mental retardation in NF to congenital malformation of the cerebral cortex (cortical dysgenesis). The incidence of seizures is about 20 times higher than that in the general population.

Exceptionally, NF has been associated with peroneal muscular atrophy, congenital deafness, and partial albinism (Bradley et al).

In childhood, progressive blindness is a particularly troublesome complication. One or both optic nerves are involved in a tumor mass composed mainly of astrocytes. The diagnosis comes to mind at once in a child with any of the cutaneous manifestations of NF. Uncertainty as to its nature arises from the fact that the neuropathologist may be unable to decide between a benign hamartoma and a grade 1 astrocytoma. Progressive enlargement in a succession of MRI scans may be needed to affirm its blastomatous nature.

**Neurofibromatosis Type 2 (Acoustic or Central NF)** This condition is considerably less frequent than type 1 NF. Here there is an absence or paucity of cutaneous lesions. Progressive deafness and the demonstration by enhanced CT or MRI of bilateral acoustic neuromas affords accurate diagnosis (see Fig. 31-16). Also, an acoustic neuroma developing before age 30 is suspect as being caused by NF 2. Other cranial or spinal neurofibromas, meningioma (sometimes multiple), and glioma may be added to the syndrome of deafness or may occur prior to its emergence. Juvenile cataracts of the subcortical or capsular variety are seen in some affected patients. Gene analysis for this entity has become available.

**Pathology of NF1 and NF2** The cutaneous tumors are characterized by a rather thin epidermis whose basal layer may or may not be pigmented. The collagen and elastin of the dermis is replaced by a loose arrangement of elongated connective tissue cells. The lack of compactness of the normal dermal collagen allows the palpable opening in the skin.

The pigmented (café au lait) lesions contain only the normal numbers of melanocytes; the dark color of the skin is due instead to an excess of melanosomes in the melanocytes. Some of the abnormally large melanosomes measure up to several microns in diameter.

The nerve tumors are composed of a mixture of fibroblasts and Schwann cells (except the optic nerve tumors, which contain a combination of astrocytes and fibroblasts). Predominance of one or the other of these cells in the nerve is the basis of the diagnosis of neurofibroma or schwannoma. Palisading of nuclei and sometimes encircling arrangements of cells (Verocay bodies) are features of both (see Chap. 31). Occasionally, along spinal roots or sympathetic chains, one may find a tumor made up of partially or completely differentiated nerve cells, a typical ganglioneuroma. Clusters of abnormal glial cells may be found in the brain and spinal cord, and, according to Bielschowsky, they imply a link with tuberous sclerosis. Clinically and genetically, however, the two diseases are quite independent.

Malignant degeneration of the tumors is found in 2 to 5 percent of cases; peripherally they become sarcomas, and centrally, astrocytomas or glioblastomas (Fig. 38-11).

**Diagnosis** If skin tumors and café au lait spots are numerous and Lisch nodules are present in the iris, the identification of the disease as type 1 neurofibromatosis offers no difficulty. A history of the illness in antecedent and collateral family members makes diagnosis even more certain. Doubt arises most frequently in patients with bilateral acoustic neuromas or other cranial or spinal neurofibromas or schwannomas with no skin lesions or only a few random ones. The tendency for these forms of NF to have few skin lesions is well known, but differentiation of type 1 from type 2 may be uncertain unless genetic studies are undertaken. Plexiform neuromas with muscle weakness, due to nerve involvement, and abnormalities of underlying bone may be confused with other tumors, especially in young children, who tend to have few café au lait spots and few cutaneous tumors. Hypertrophy of a limb, which may also occur, requires differentiation from other developmental anomalies.

As already mentioned, Crowe and coworkers have expressed the view that 80 percent of patients with von Recklinghausen disease can be diagnosed by the presence of more than six café au lait spots. Of the remaining 20 percent, those over 21 years of age will be found to have multiple cutaneous tumors, axillary freckling, and a few pigmented spots; in those under 21 with no dermal tumors.
and only a few café au lait patches, a positive family history and radiographic demonstration of bone cysts will be helpful in some instances. Café au lait spots and cutaneous tumors should always be sought, for they may help the neurologist diagnose an otherwise obscure progressive spinal syndrome, a cerebellopontine angle syndrome, bilateral deafness, progressive blindness, and an occasional case of precocious puberty, hydrocephalus, or mental retardation.

Because of the many conditions that accompany classic NF and because they are potentially dangerous, the initial clinical evaluation should be supplemented by a number of ancillary examinations: measurement of IQ, EEG, slit-lamp examination of irides, radiography of optic foramen s and internal auditory meati, visual and auditory evoked responses, and CT scans or MRI of cranium and sometimes of spine and mediastinum. In the series of Duffner and colleagues, 74 percent of cases had abnormal signals in T2-weighted images of the basal ganglia, thalamus, hypothalami, brainstem, and cerebellum. The EEG was abnormal in 25 percent. If there is suspicion of a pheochromocytoma, a 24-h urine should be tested for metabolites of epinephrine. Each of these tests not only is an aid to diagnosis but is also essential to the intelligent management of the illness.

**Treatment** The skin tumors should not be excised unless they are cosmetically objectionable or show an increase in size, suggesting malignant change. The effects of radiotherapy on these lesions are so insignificant that they do not justify the risk of exposure. Plexiform neuromas about the face pose especially difficult problems. Here one must resort to plastic surgery, but the results are not always satisfactory because the growths may implicate cranial nerves superficially (with risk of greater paralysis after surgical excision) or alter the underlying bone, the latter being either eroded from pressure or hypertrophied from increased blood supply. Cranial and spinal neurofibromas are amenable to excision, and the gliomas and meningiomas usually demand surgical measures as well. Here the differentiation of hamartomas from gliomas of structures such as the optic nerves, hypothalamus, or pons may be difficult. Bilateral optic nerve gliomas are usually treated with radiation; unilateral ones are excised. Peripheral nerve tumors that have undergone malignant (sarcomatous) degeneration pose special surgical problems.

Affected individuals should be advised not to have children— a precaution that may not be necessary, because fertility, especially in males, seems to be reduced by the disease. Prognosis varies with the grade of severity, being most favorable in those with only a few lesions. But the disease is always progressive, and the patient should remain under continuous surveillance.

**Familial schwannomatosis** As commented in Chap. 31 in the discussion of acoustic neuroma, it is now apparent that the propensity to develop multiple schwannomas can also be inherited as a dominant trait, without the vestibular tumors characteristic of NF2. This trait maps to a genetic locus on chromosome 22 that is distinct from the one for NF2.

**Other Cutaneous Angiomatoses with Abnormalities of the Central Nervous System**

There are at least seven diseases in which a cutaneous or ocular vascular anomaly is associated with an abnormality of the nervous system: (1) meningo- or encephalofacial (encephalotrigeminal) angiomatosis with cerebral calcification (Sturge-Weber syndrome); (2) dermatomal hemangiomas and spinal vascular malformations (sometimes with limb hypertrophy, as also occurs in Klippel-Trenaunay-Weber syndrome and in neurofibromatosis); (3) the epidermal nevus (linear sebaceous nevus) syndrome; (4) familial telangiectasia (Osler-Rendu-Weber disease); (5) hemangioblastoma of cerebellum and retina (von Hippel-Lindau disease); (6) ataxia-telangiectasia (Louis-Bar disease); and (7) angiookeratosis corporis diffusum (Fabry disease). The last three disorders are considered elsewhere: ataxia-telangiectasia and Fabry disease with the inherited metabolic disorders (pages 839 and 1159, respectively) and von Hippel-Lindau disease are discussed below and with hemangioblastoma (page 568).
Meningo- or Encephalofacial Angiomatosis with Cerebral Calcification (Sturge-Weber Syndrome) The vascular nevus is observed at birth to cover a large part of the face and cranium on one side (in the territory of the ophthalmic division of the trigeminal nerve). In one-quarter of the cases the nevus is bilateral. The lesions vary in extent, the most limited being an involvement of only the upper eyelid and forehead and the most extensive being the entire head and even other parts of the body. The nevus is deep red (port-wine nevus), and its margins may be flat or raised; soft or firm papules, evidently composed of vessels, cause surface elevations and irregularities. Orbital tissue, especially the upper eyelid, is almost invariably involved; congenital buphthalmos may enlarge the eye before birth and glaucoma may develop later in that eye, causing blindness. The choroid is implicated in some cases. The increased cutaneous vascularity may result in an overgrowth of connective tissue and underlying bone, giving rise to a deformity like that of the Klippel-Trenaunay-Weber syndrome. Indications of cerebral affection appear as early as the first year of life or later in childhood; the most frequent clinical manifestations are unilateral seizures followed by increasing degrees of spastic hemiparesis with smallness of the arm and leg, hemisensory defect, and homonymous hemianopia, all on the side contralateral to the trigeminal nevus. Skull films (usually normal just after birth) taken after the second year reveal a characteristic “tramline” calcification, which outlines the convolutions of the parieto-occipital cortex. CT scanning and MRI have shown the abnormalities of the involved cortex at an earlier age.

This condition is generally referred to as the Sturge-Weber syndrome, since it was W. Allen Sturge who, in 1879, described a child with sensorimotor seizures contralateral to a facial “port-wine mark,” and Parkes Weber (1922, 1929), who gave the first radiographic demonstration of the atrophy and calcification of the cerebral hemisphere homolateral to the skin lesion. This eponym overlooks the important intervening contributions of Kalischer (1897, 1901), who first described the meningial angioma in conjunction with the facial one; of Volland (1913), who demonstrated the intracortical calcific deposits; and of Dimitri (1923), who described the characteristic double-contoured radiographic shadows. Krabbe (1932, 1934) showed conclusively that the calcification lay not in the blood vessels (as Dimitri and many others had concluded) but in the second and third layers of the cortex (see Wohlwill and Yakovlev for historical review and bibliography).

It must not be thought that all cranial hemangiomas affect the cerebrum; the common facial nevi, especially the flat midline ones and the elevated strawberry nevi, are of no neurologic significance. And a cerebral-meningeal angiomatosis may be present without skin lesions. The involvement of the upper eyelid is of greatest importance; nearly all such cases are associated with cerebral lesions (Barlow). There seems to be a close correlation between the persistence or maldevelopment of the embryonic vascular plexus of the eyelid and forehead and that of the occipitoparietal parts of the brain. When the nevus lies entirely below the upper eyelid or high on the scalp, a cerebral lesion is usually absent, although in a few instances such an angioma has been associated with a vascular malformation of the meninges overlying the brainstem and cerebellum. In angiograms, the abnormal meningeal vessels, which are largely veins, are not well seen; thus they can be distinguished from arteriovenous malformations. These purely meningeal venous nevi are rarely the source of subarachnoid or cerebral hemorrhage, and they do not enlarge to form a mass. The cortical lesion is, however, destructive of cortical tissue, which is replaced by glial tissue that calcifies. Possibly, diversion of blood to the meninges during seizures causes a progressive ischemia of the cerebral cortex. Barlow has stated that the seizures themselves are responsible for the progressive neurologic deficits and that a special effort should be made to prevent them by carefully regulated medical therapy. Occasionally surgical excision of intractable discharging foci may be necessary, but often this may not be feasible in view of the magnitude of the cerebral lesion. Radiotherapy is unsuccessful in reducing the skin blemish; sensitive individuals usually try to hide it with cosmetics.

Although the encephalotrigeminal syndrome is of congenital origin, its cause and pathogenesis are unknown. Familial coincidence has been observed but is exceptional. No chromosomal abnormality has been demonstrated.

Dermatomal Hemangiomas with Spinal Vascular Malformations A hemangioma of the spinal cord may rarely be accompanied by a vascular nevus in the corresponding dermatome, as was first pointed out by Cobb. Such nevi are most frequent on the arm and trunk. When the cutaneous lesion involves an arm or leg, there may be enlargement of the entire limb or fingers in combination with underdevelopment of certain other parts (Klippel-Trenaunay-Weber syndrome). Some of these angiomatous syndromes combine a spinal or retinodiencephalic arteriovenous malformation (AVM) with a nevus of the trunk or face, respectively. Such cases provide a link to the common AVMs described in Chap. 34.

Epidermal Nevus Syndrome This is a closely related congenital neurocutaneous disorder in which a specific skin lesion (epidermal nevus or linear sebaceous nevus) is associated with a variety of hemicranial and neurologic abnormalities. The skull and brain abnormalities are ipsilateral to the nevus. One-sided thickening of the bones of the skull is characteristic. Mental retardation, seizures, and hemiparesis are the usual neurologic manifestations and have their basis in a wide variety of cerebral lesions—unilateral cerebral atrophy, porencephalic cyst, leptomeningeal hemangioma, arteriovenous malformation, and atresia of cerebral arteries and veins. The somatic and neurologic abnormalities of this syndrome have been comprehensively reviewed by Solomon and Esterley and by Baker and associates.

Hereditary Hemorrhagic Telangiectasia (Osler-Rendu-Weber Disease) This vascular anomaly is transmitted as an autosomal dominant trait. It affects the skin, mucous membranes, gastrointestinal and genitourinary tracts, lungs, and occasionally the nervous system. The basic lesion is probably a defect in the vessel wall, and the main complication, bleeding, is thought to be due to the mechanical fragility of the vessel. Located sparsely in the skin of any part of the body, these vascular lesions first appear during childhood, enlarge during adolescence, and may assume spideriform, resembling the cutaneous telangiectasias of cirrhosis in late adult life. The lesions range from the size of a pinhead to 3 mm or more, are bright red or violaceous, and blanche under pressure.

The significance of the lesions lies in their hemorrhagic tendency. During adult years they may give rise to severe and repeated epistaxis or gastric, intestinal, or urinary tract bleeding and result in an iron-deficiency anemia. Pulmonary fistulas constitute another important feature of the generalized vascular dysplasia; patients with such lesions are particularly subject to brain abscesses and less so to bland embolic strokes.
The angiomas of this disease may form in either the spinal cord or brain, where they can produce apoplectic syndromes; or as in one of our patients, there may be an intermittently progressive focal thalamic syndrome resulting from enlargement of the vascular lesions (or possibly from a succession of small hemorrhages). An unexplained gastrointestinal, genitourinary, intracranial, or intraspinal hemorrhage warrants a search for small cutaneous lesions, which are easily overlooked. Satellite lesions tend to form after obliteration of an angioma.

To date, two mutant genes have been identified as causes of this disease: endoglin and novel kinase.

von Hippel-Lindau Disease (See also page 568) This is a genetic disease of multiple neoplasms, specifically identified by the presence of a hemangioblastoma, sometimes multiple (these are discussed with other cerebral tumors in Chap. 31). The tumor is situated in the cerebellum in most cases but may also arise in the brainstem or spinal cord. In addition to the characteristic cerebellar tumor with its nodule within a cyst, half of these patients have retinal hemangioblastomas and somewhat fewer develop renal cell cancer; an even smaller number have a pheochromocytoma, pancreatic tumors or cysts, or cystadenomas. Polycythemia vera is an interesting feature in a few cases.

The cerebellar hemangioblastoma typically develops in the fourth decade and causes symptoms of ataxia and headache. On imaging studies, the lesions have a striking appearance of a cyst with a nodule contained in its wall, and angiography demonstrates the highly vascular nature of the nodule, which represents the actual neoplasm (Fig. 31-13). The other identifying features of the disease, retinal hemangiomas, are indistinguishable histologically from the craniospinal ones. They are multiple and bilateral, usually appearing earlier than the cerebellar lesions but remaining asymptomatic until they become extensive (retinal detachment is one feature). Their diagnosis is made by funduscopy, by which a large feeding vessel leading to an irregularly shaped ovoid tumor in the retina can usually be appreciated. Imaging studies of the cranium that use dye enhancement will reveal this as well.

Inheritance is autosomal dominant with variable but high penetrance by older age. The causative mutation is in the so-called VHL gene located on chromosome 3. This is a tumor suppressor gene that is inactivated by the mutation and may induce oncogenesis by increasing the expression of vascular mitogenic factors such as vascular endothelial growth factor (VEGF); the precise mechanisms are not known. Renal cell cancer is a serious component of the disease, occurring in up to 60 percent of cases, but the tumors, while multiple, tend initially to be small and of low grade. Nonetheless, renal cancer accounts for one-third of deaths from the disease, the remainder being due largely to complications of the cerebellar neoplasm. An extensive review of the subject is given by Losner and colleagues.

### RESTRICTED DEVELOPMENTAL ABNORMALITIES OF THE NERVOUS SYSTEM

In the course of clinical practice, one encounters a remarkable number of restricted disorders of the nervous system, many of which are transmitted from generation to generation as a mendelian, usually dominant trait. Of the more severe ones, only a few of the more striking examples are described here. Milder and more restricted conditions such as stuttering and dyslexia are described in Chap. 28. The reader may turn to books on genetics or teratology for an account of such oddities as hereditary unilateral ptosis, hereditary Horner syndrome (see page 464), pupillary inequalities, jaw winking, absence of a particular muscle, etc.

**Bifacial and Abducens Palsies (Möbius Syndrome)** The syndrome of congenital facial diplegia with convergent strabismus is generally referred to as *Möbius syndrome*, although it had been described earlier by von Graefe. Its presence at birth is disclosed by the lack of facial movements and of full eye closure. The most complete review of the subject in the English literature is that of Henderson, and a recent analysis of 37 affected individuals has been given by Harriëtte and colleagues. In Henderson’s study of 61 cases of the congenital facial diplegia syndrome, there were 45 instances of an associated abducens palsy, 15 of complete external ophthalmoplegia, 18 of lingual palsy, 17 of clubfeet, 13 of a brachial disorder, 6 of mental defect, and 8 of an absent pectoral muscle. Thus the overlap with other neuromuscular and CNS abnormalities is evident. Harriëtte and coworkers emphasize the frequency of hypoplastic or dysplastic tongue, palatal involvement, and general motor clumsiness. They suggest that the disorder represents a widespread form of brainstem maldevelopment.

Early in life the mouth hangs open, the lower lip is everted, and there is difficulty in sucking. Usually this syndrome can be distinguished from the facial palsy of forceps or birth injury by its bilaterality and the other associated weaknesses. Occasionally more than one family member is affected (usually autosomal dominant inheritance). The cause of this peculiar condition is not known. The few adequate pathologic studies have shown a lack of nerve cells in the motor nuclei of the brainstem, changes that also characterize the Fazio-Londe type of muscular dystrophy (page 947). Rarely, there may be an aplasia of facial muscles. The Möbius syndrome is also referred to on page 1246 in relation to restricted palsies of myopathic and nuclear origin.

Partial paralysis of facial muscles that dates from birth and cannot be attributed to obstetric trauma is not infrequent. In a common type, the lower lip on one side remains immobile when the child smiles or cries; the lip on the unaffected side is drawn downward and outward, resulting in a prominent asymmetry of the lower face. Often it is not appreciated that the side that droops during crying is the normal side (Hoefnagel and Penny).

**Congenital Lack of Lateral Gaze (Oculomotor Apraxia of congenital type)** (See page 228) Children with this congenital defect are unable to turn their eyes to either side voluntarily or on command. Attempting to look to the right, the child turns the head to the right (there is no associated apraxia of head turning, as in acquired apraxia), but the eyes lag and turn to the left. As a result, the patient has to overshoot the mark with the head in order to attain ocular fixation. Once the eyes fixate, the head returns to the primary position. To compensate for the deficiency of eye movements, the patient develops jerky thrusting movements of the head, which characterize all attempts at voluntary gaze. Caloric stimulation of the labyrinth causes tonic movement of the eyes but not nystagmus, as in the normal person. Also, optokinetic nystagmus cannot be induced. Vertical eye movements are normal. A similar ocular condition may occur in conjunction with ataxia-telangiectasia and Gaucher disease. Children with oculomotor apraxia are slow to walk; Ford observed one such child whose sibling had an absence of the vermis of the cerebellum. Aside from
this observation, the anatomic basis of the condition has not been studied.

**CONGENITAL ABNORMALITIES OF MOTOR FUNCTION (CEREBRAL PALSY)**

In this group of congenital disorders, a major disturbance of motor function, usually nonprogressive, has been present since infancy or early childhood. The popular terms for these conditions have been *infantile cerebral paralysis* (Freud) and *cerebral palsy*. The latter name is not appropriate, nor is it useful from the physician’s viewpoint, collocating as it does diseases of widely differing etiologic and anatomic types, wherein the hereditary and acquired and the intrauterine, natal, and postnatal diseases lose their identity. But the name has been adopted as a slogan by fund-raising societies and for all manner of rehabilitation clinics throughout the United States, hence it will not soon disappear from medical terminology. The term, often abbreviated CP, is still being used indiscriminately by many physicians to designate every conceivable cognitive and motor disorder of corticospinal, extrapyramidal, cerebellar, and even neuromuscular type in infants and children.

**Etiology of the Congenital Cerebral Motor Disorders**

Motor abnormalities that have had their onset early in life are numerous and diverse in their clinical manifestations. Marked prematurity is a determining factor in a large proportion of cases. Each year, about 50,000 infants weighing less than 1500 g are born in the United States. Approximately 85 percent survive. Of these, 5 to 15 percent have a motor disorder of cerebral origin and 25 to 30 percent are found to be mentally impaired at school age (Volpe; see also Hack et al). To ascertain the etiologic and pathogenic factor(s), it is helpful to categorize a given case according to the extent and nature of the motor abnormality. A careful history of possible prenatal, perinatal, or postnatal insults to the developing nervous system must always be sought; certain correlations of these factors with the resulting pattern of neurologic deficit are outlined below. Most patients with these motor abnormalities of infancy and childhood reach adult years. Many but not all have some degree of mental retardation and epilepsy in addition to the motor abnormality. A careful history of possible causes and mechanisms of these three clinical states.

The following discussion of these problems is centered on the three major etiologic syndromes—matrix hemorrhages in the immature infant, hypoxic-ischemic encephalopathy (Little disease), and certain developmental motor abnormalities.

**Germinal Matrix (Subependymal) Hemorrhage in Premature Infants**

In low-weight and premature immature infants (20 to 35 weeks gestational age), there sometimes occurs, within a few days after birth, a catastrophic decline in cerebral function, usually preceded by respiratory distress (hyaline membrane disease), with spells of cyanosis and apnea. Also evident are failure of brainstem automatisms (sucking and swallowing), bulging of the fontanelles, and appearance of sanguineous CSF. If the infant becomes completely unresponsive, death usually ensues within a few days. Autopsy discloses a small lake of blood in each cerebral hemisphere (often asymmetrically distributed), occupying the highly cellular (subependymal) germinal matrix zone, near the caudate nucleus at the level of the foramen of Monro. This region is supplied by the lenticulostriate, choroidal, and Heubner’s recurrent arteries and is drained by deep veins, which enter the vein of Galen. In about 25 percent of cases, the blood remains localized in the matrix zone, while in the others it ruptures into the lateral ventricle or adjacent brain tissue. In a series of 914 consecutive autopsies in newborns, subependymal hemorrhage was found in 284 (31 percent); practically all of these neonates were of low birth weight (Barker and Bruce-Gregorios).

Lesser degrees of this complex of cerebral lesions are now being identified by ultrasonography (Fig. 38-12) and CT scans, and it is apparent that many infants with smaller hemorrhages survive. Some rapidly develop an obstructive hydrocephalus and require a ventricular shunt. In others, the hydrocephalus stabilizes and there is clinical improvement. Several series of surviving cases have now been followed for many years. Those in whom the hemorrhage was more extensive are often left with motor and intellectual handicaps.

Just over half of the patients in the Swedish series of Hagberg and Hagberg, with spastic diplegia, had matrix hemorrhages, leukomalacia (see further on), or both. Congenital hemiplegia or quadriplegia was observed at a lower frequency. In another series of 20 cases of posthemorrhagic hydrocephalus (Chaplin et al), 40 percent had significant motor deficits and over 60 percent had IQ scores of less than 85. In an experience with 12 less severely affected surviving cases (mean birth weight 1.8 kg and gestational age of 32.3 weeks), R. D. Adams noted that only one had a residual spastic diplegia and 9 of the 12 had IQs in the low-normal or normal range.

The cause of matrix hemorrhage is not entirely clear. In all probability it is related to greatly increased pressure in the thin-walled veins of the germinal matrix coupled with a lack of adequate supporting tissue in these zones. During periods of unstable arterial or venous blood pressure that occur with the pulmonary disorders of immature infants, these thin-walled vessels rupture. These infants are also prone to the development of another characteristic lesion of the cerebral white matter (periventricular leukomalacia, probably of venous origin; see below), and the neurologic deficits resulting from these lesions may be added to the residual deficits due to the subependymal hemorrhage (mainly hydrocephalus).

**Treatment**

Control of the respiratory distress of prematurity may reduce the incidence of matrix hemorrhages and periventricular leukomalacia. Claims have been made that the administration of indomethacin ethamsylate, a drug that reduces capillary bleeding, and the intramuscular injection of vitamin E for the first 3 days after birth and possibly the use of betamethasone or other corticosteroids appears to be of value in reducing the incidence of periventricular hemorrhage (Benson et al; Sinha et al; see also Volpe

![Figure 38-12. Ultrasound demonstration of subependymal matrix hemorrhage in a premature infant (arrow).](image-url)
for discussion of control of cerebral hemodynamics and effects of medications in the neonatal period). Acetazolamide and furosemide, which reduce the formation of spinal fluid, have been widely used in the treatment of posthemorrhagic hydrocephalus. However, in a large-scale controlled study, the effects were negligible and shunt placement was required to control worsening hydrocephalus (see International PHVD Drug Trial Group in the References).

Periventricular Leukomalacia These are zones of necrosis of white matter in the deep watershed territories of cortical and central arteries. They lie lateral and posterosilateral to the lateral ventricles, in a position to involve the occipital radiations and the sensorimotor fibers in the corona radiata (first described by Banker and Larroche; see also Shuman and Selednik). The white matter lesions occur in about one-third of cases of subependymal hemorrhage (see above), but they may develop independently in both premature and full-term infants who have suffered hypotension and apnea. In a study of 753 preterm infants, those born at 28 weeks gestation were at highest risk of this complication; the combination of intraventricular infection and premature rupture of membranes carried a 22 percent risk (Zupan et al). Survivors often manifest cerebral hemiplegia or diplegia and variable degrees of mental impairment. The motor disorder is usually more severe than the cognitive and language impairment. Increasingly, small lesions of this nature are being identified in term infants.

The mechanism of this type of periventricular infarction has been debated and the terminology and clinical features, insofar as they overlap with germinial matrix hemorrhage, have been confusing. In recent years, most theories and experimental evidence converge on the notion that these represent venous infarctions. By ultrasonographic examination, the lesions appear as an echodensity in the periventricular white matter. They are also visible by MRI.

Hypoxic-Ischemic Damage and Neonatal Encephalopathy Little’s conception of the hypoxic-ischemic form of “birth injury,” enunciated in 1862, has been scrutinized over the years. While it is evident that many newborns suffer some degree of perinatal asphyxia, relatively few seem to manifest brain damage. Moreover, many infants with a variety of cerebral motor syndromes appear to have passed the parturitional (perinatal) period without mishap, indicating the greater importance of other perinatal and postnatal causative factors. Nonetheless, severe neonatal asphyxia of term or preterm babies can be an important cause of spastic-dystonic ataxic syndromes, often accompanied by seizures and mental subnormality.

One has the impression that the CNS tolerates hypoxia and reduced blood flow in the immediate postnatal period better than at any other time in life. Indeed, animal experimentation supports this view. Not until the arterial oxygen tension is reduced dramatically to 10 to 15 percent of normal does brain damage occur, and even then the impaired function of other organs contributes to the damage. Nearly always there are irregularities of the heart and hypotension from myocardial damage as well as hepatic and renal failure. Thus it is more correct to think of the encephalopathy in terms of both hypoxia and ischemia, which usually occur in utero and are expressed postnatally by recognizable clinical syndromes.

Fenichel, following the original work of Sarnat and Sarnat in 1976 and of Levene and colleagues, finds it helpful to divide the cerebral syndromes that follow a difficult birth into three groups, according to their severity, each having a greater prognostic value than the Apgar score: (1) In newborns with mild hypoxic-ischemic encephalopathy, the symptoms are maximal in the first 24 h and take the form of hyperalertness and tremulousness of the limbs and jaw (the “jittery baby”) and a low threshold of the Moro reaction. The tone of the limbs is normal except for a mild increase in head lag during traction. The reflexes are brisk and there may be ankle clonus. The anterior fontanel is soft. The EEG is normal. Recovery is usually complete and the risk of handicap is low. (2) Newborns with moderate hypoxic-ischemic encephalopathy are lethargic, obtunded, and hypotonic, with normal movements. After 48 to 72 h, the neonate may improve (having passed through a jittery hyperactive phase) or worsen, becoming less responsive in association with convulsions, cerebral edema, hyponatremia, and hyperammonemia from liver damage. The EEG is abnormal; Fenichel associates epileptiform activity and voltage suppression with an unfavorable outcome. Abnormal visual and auditory evoked potentials are other poor prognostic signs. (3) In neonates with severe hypoxic-ischemic encephalopathy, stupor or coma is present from birth; respirations are irregular, requiring mechanical ventilation. There are usually convulsions within the first 12 h. The limbs are hypotonic and motionless even during attempts to elicit the Moro response. Sucking and swallowing are depressed or absent, but pupillary reactions and eye movements may at first be retained, only to be lost as the coma deepens.

It is in the second and third categories, i.e., the states of moderate to severe encephalopathy, where correction of the respiratory insufficiency and the metabolic abnormalities permits survival, that a number of motor abnormalities (corticospinal, extrapyramidal, and cerebellar) and mental retardation eventually emerge. Included in the category of severe hypoxic-ischemic encephalopathy are also newborns with a variety of developmental anomalies of the brain and other organs. In addition, such infants may have been exposed to certain prenatal risk factors (toxemia of pregnancy, antepartum uterine hemorrhage), or their growth may have been abnormal (small-for-date babies). Some are born at term; others are premature, and the birth process may or may not have been abnormal. One must then consider the possibility, originally pointed out by Sigmund Freud, that the abnormality of the birth process, instead of being causal, was actually the consequence of prenatal pathology. The latter might include preterm intrapartum hypoxia-ischemia.

Other evidence of multifactorial etiology in the “causation” of cerebral palsy has been provided by Nelson and Ellenberg, who found that maternal mental retardation, birth weight below 2000 g, and fetal malformation were among the leading predictors. Breech presentation was another factor, and one-third of these cases also had some noncerebral malformation. Twenty-one percent of the 189 children in their series had also suffered some degree of asphyxia. Additional determinants were maternal seizures, a motor deficit in an older sibling, two or more prior fetal deaths, hyperthyroidism in the mother, pre-eclampsia, or eclampsia. In children with cerebral diplegia born at term, likely contributory factors that were operative in nearly half included toxemia of pregnancy, low birth weight for age, placental infarction, and intrapartum asphyxia.

The factors enumerated above are involved to different degrees in the outcome of pregnancies but are informative because they bring to light the significant proportion of cases of cerebral birth injury in which hypoxia-ischemia, matrix hemorrhages, and leukomalacia were not operative. In this group, we would also include the symmetrical porencephalies and hydranencephalies.

Thus the complexity of assigning a cause for cerebral palsy is evident. In respect to the motor disorders discussed below,
hypoxic-ischemic perinatal injury is still the most commonly specified cause of neonatal encephalopathy but is often unrelated to a permanent defect of cerebral palsy. This statement has been amply confirmed by a large and often cited study from Western Australia that detected neonatal encephalopathy in 3.8 of 1000 term births but was able to identify causative intrapartum factors alone in only 5 percent (Badawi et al). Furthermore, only 10 percent of all the infants with neonatal encephalopathy developed spastic quadriplegia, according to Evans and colleagues. In another recent study, Cowan and colleagues used MRI to determine the proportion of infants with a neonatal encephalopathy who had antenatal brain injury. Excluding those with major congenital malformations or obvious chromosomal abnormalities, 80 percent of cases had no established lesion or brain atrophy. In contrast, those with only seizures and no neonatal encephalopathy in 69 percent of cases had evidence of antenatal damage on MRI; infarctions due to thrombotic disorders were most common. In conclusion, these studies at least demonstrate the utility of MRI in identifying neonatal forms of encephalopathy. Causing added difficulty is the fact that the clinical signs of perinatal injury may emerge only when the maturation process of the nervous system exposes them at a later period of life.

This field has been complicated by an unprecedented rise in malpractice litigation, spawned in part by the belief that early detection of asphyxia and rapid delivery would have prevented the motor, epileptic, and cognitive problems of birth injury. The fallacy of this assumption is highlighted both by the above comments and by the observation that the incidence of cerebral palsy has not changed in term infants over the past 30 years, despite the institution of fetal monitoring and more frequent cesarean sections.

**Clinical Syndromes of Congenital Spastic Motor Disorders**

The most frequent motor disorder evolving from the four major categories of neonatal cerebral disease—matrix hemorrhage, periventricular leukomalacia, hypoxic-ischemic encephalopathy, kernicterus (discussed further on)—is spastic diplegia; i.e., a motor disturbance that is severe in the lower limbs and mild in the upper, as discussed below. In addition, hypoxic-ischemic injury occurring in the term or preterm infant may take the form of a hemiplegia, double hemiplegia (quadriplegia), or a mixed pyramidal-extrapyramidal or spastic-ataxic syndrome.

A second form of motor disorder is characterized by the development of severe spastic quadriplegia and mental retardation. The major insult is usually intrapartum asphyxia and attendant fetal distress. Usually such infants will have required resuscitation and will have had low 5-min Apgar scores and seizures, which in this circumstance have important predictive value. The pathologic lesions of the brain in this second group consist of hypoxic-ischemic infarction in distal fields of arterial flow, primarily in the cortex and white matter of parietal and posterior frontal lobes, leaving a ulegeric sclerotic cortex.

A third group, discussed below, is characterized mainly by extrapyramidal abnormalities, combining athetosis, dystonia, and ataxia in various proportions. After reviewing the results of several large series of congenital and neonatal motor disorders, we have concluded that spastic diplegia occurs in 10 to 33 percent of cases, spastic quadriplegia 19 to 43 percent, extrapyramidal forms in 10 to 22 percent, and mixed forms in 9 to 20 percent.

**Spastic Diplegia (Little Disease)** The pattern of paralysis is more variable than the term spastic diplegia implies; actually, several subtypes may be distinguished: the paraplegic, diplegic, quadriplegic, pseudobulbar, and generalized. Pure paraplegic and pseudobulbar types are relatively rare. Usually all four extremities are affected, but the legs much more than the arms, which is the real meaning of diplegia. Hypotonia—with retained tendon reflexes and hypoactivity—is usually present initially. Only after the first few months will evident weakness and spasticity appear, first in the adductors of the legs. The plantar reflexes, which are often ambiguous in the normal infant, here are clearly extensor, a finding that is pathologic at any later age. Also, stiff, awkward movements of the legs, which are maintained in an extended, adducted posture when the infant is lifted by the axillae, often do not attract attention until several weeks or months have passed. Seizures occur in approximately one-third of the cases, and it is not uncommon to observe a delay in all developmental sequences, especially those that depend on the motor system.

Once walking is attempted, usually at a much later date than usual, the characteristic stance and gait become manifest. The slightly flexed legs are advanced stiffly in short steps, each describing part of an arc of a circle; addition of the thighs is often so strong that the legs may actually cross (scissors gait); the feet are flexed and turned in with the heels not touching the floor. In the adolescent and adult, the legs tend to be short and small, but the muscles are not markedly atrophic, as in spinal muscular atrophy. Passive manipulation of the limbs reveals spasticity in the extensors and adductors and slight shortening of the calf muscles. The arms may be affected only slightly or not at all, but there may be awkwardness and stiffness of the fingers and, in a few, pronounced weakness and spasticity. In reaching for an object, the hand may overpronate and a grasp may be difficult to release. Speech may be well articulated or noticeably slurred, and in some instances the face is set in a spastic smile. The deep tendon reflexes are exaggerated, those in the legs more than the arms; the plantar reflexes are extensor in the majority of cases. Scoliosis is frequent and may secondarily give rise to root compression and impaired respiratory function. As a rule, there is no disturbance of sphincteric function, though delay in acquiring voluntary control is usual. Athetotic postures and movements of the face, tongue, and hands are present in some patients and may actually conceal the spastic weakness; ataxic and hypotonic forms also exist (see further on).

One subtype of spastic diplegia is associated with a relatively slight diminution in head size and of intelligence. As indicated above, there is no unifying neuropathology; the condition occurs independently of matrix hemorrhages and periventricular leukomalacia as well as with them. The frequency of cerebral spastic diplegia, which is closely related to the degree of prematurity, has declined significantly since the introduction of neonatal intensive care facilities, and there is reason to believe that heredogenous factors are now of more importance.

**Infantile Hemiplegia, Paraplegia, and Quadriplegia** Hemiplegia is a common condition of infancy and early childhood. The functional difference between the two sides may be noticed soon after birth, but more often it is not perceived by the mother until after the first 4 to 6 months of life. In a second group, the child is in excellent health for a year or longer before the abrupt onset of hemiplegia (see below). In hemiplegia that dates from earliest infancy—i.e., congenital hemiplegia—the parents first notice that movements of prehension and exploration are carried out with only one arm. A manifest hand preference at an early age should always raise the suspicion of a unilateral motor defect. The affection of the leg is usually recognized later, i.e., during the first attempts to stand and walk. Sitting and walking are usually delayed by a few
months. In the older child, there is evident hyperactivity of tendon reflexes and usually a Babinski sign. The arm is held flexed, adducted, and pronated, and the foot assumes an equinovarus posture. Sensory and visual field defects can be detected in some patients. Mental defect may be associated with infantile hemiplegia but is less common and lesser in degree than with cerebral diplegia and much less common than with bilateral hemiplegia. There may also be speech delay, regardless of the side of the lesion; when this is present, one should look for mental retardation and expect to find a bilaterality of motor abnormality. Convulsions occur in 35 to 50 percent of children with congenital hemiplegia, and these may persist throughout life. They may be generalized but are frequently unilateral and limited to the hemiplegic side (or the contralateral side if the hemiplegia is severe). Often, after a series of seizures, the weakness on the affected side will be increased for several hours or longer (Todd’s paralysis). Gastaut and associates have described a hemiconvulsive-hemiplegic syndrome in which the progressive paralysis and cerebral atrophy are attributed to the convulsions. As months and years pass, the osseous and muscular growth of the hemiplegic limbs is retarded, leading to an obvious hemiatrophy.

With respect to the causation of congenital hemiplegia, it is generally agreed that perinatal asphyxia is only one of the possibilities. In the series of 681 children with “cerebral palsy” collected by Hagberg and Hagberg, there were 244 with hemiplegia. Of the latter, 189 were full-term babies and 55 preterm. Prenatal risk factors were identified in only 45 percent, and they were mostly in the infants born prematurely. In nearly half of the cases, there was no clue as to the time in the intrauterine period when the cerebral lesion occurred.

In another group—*acquired infantile hemiplegia*—a normal infant or young child, usually between the ages of 3 and 18 months, develops a massive hemiplegia, with or without aphasia, within hours. The disorder often begins with seizures, and the hemiplegia may not be recognized until the seizures have subsided. In Banker’s autopsy series, there was arterial or venous thrombosis in some cases, but instances without vascular occlusions were found. Some of the latter cases, in which arteriography had been normal, may have been embolic, possibly of cardiac origin. In the recent era, imaging has shown a large area of cerebral infarction, not dissimilar to a stroke in the territory of the middle cerebral artery, acquired during infancy but usually with a normal arteriogram (Fig. 38-13). If the stroke occurs at an early age, the recovery of speech may be complete, though reduced scholastic capacity remains. The degree of recovery of motor function varies. Often, as the deficit recedes, the arm becomes involved by athetotic, tremulous, or ataxic movements; there may be an interval of months or years between the hemiplegia and the athetosis.

Encephaloclastic (destructive) lesions underlie most of the cases of infantile hemiplegia and some cases of bilateral hemiplegia (as well as many cases of seizures in the first few days of life). The pathologic change is essentially that of ischemic necrosis. In many cases, the lesions must have been acquired in utero. Precipitant delivery, fetal distress, and prepartum uterine hemorrhage may have been indications of the process. The lesions seemingly reflect those of circulatory insufficiency (ischemia), the result of hypotension or local circulatory failure. What is most notable is that the ischemia tends to affect the tissues lying in arterial cortical border zones; there may also be venous stasis with congestion and hemorrhage occurring particularly in the deep central structures, such as the basal ganglia and periventricular matrix zones. If they are purely hypoxic, the lesions should be bilateral. Myers has reproduced such lesions in the neonatal monkey by reducing the maternal circulatory (Fig. 38-13). As the lesions heal, the monkeys develop the same sclerotic changes in the cortex and white matter of the cerebrum (lobar sclerosis) and the “marbling” (état marbré) that characterizes the brains of patients with spastic diplegia and double athetosis (see below).

The quadriplegic state differs from bilateral hemiplegias in that the bulbar musculature is often involved in the latter and mental retardation is more severe. The condition is relatively rare and is usually due to a bilateral cerebral lesion. However, one should also be alert to the possibility of a high cervical cord lesion. In the infant, this is usually the result of a fracture dislocation of the cervical spine incurred during a difficult breech delivery. Similarly, in paraplegia, with weakness or paralysis limited to the legs, the lesion may be either a cerebral or a spinal one. Sphincteric disturbances and a loss of somatic sensation below a certain level on the trunk always point to a spinal localization. Congenital cysts, tumors, and diastematomyelia are more frequently causes of paraplegia than of quadriplegia. Another recognized cause of infantile paraplegia is spinal cord infarction from thrombotic complications of umbilical artery catheterization.

**Extrapyramidal Syndromes** The spastic cerebral diplegias discussed above shade almost imperceptibly into the congenital extrapyramidal syndromes. Patients with the latter syndromes are found in every cerebral palsy clinic, and ultimately they reach adult neurology clinics as well. Corticospinal tract signs may be completely absent, and the student, familiar only with the syndrome of pure spastic diplegia, is always puzzled as to their classification. Some cases of extrapyramidal type are undoubtedly attributable to severe perinatal hypoxia and others to diseases such as erythroblastosis fetalis with kernicterus. In order to state the probable path-
ologic basis and future course of these illnesses, it is desirable to separate the extrapyramidal syndromes of prenatal-natal origin (which usually become manifest during the first year of life) from the acquired or hereditary postnatal syndromes, such as familial athetosis, Wilson disease, dystonia musculorum deformans, and the hereditary cerebellar ataxias, which become manifest later.

**Double Athetosis** This is probably the most frequent of the congenital extrapyramidal disorders. In our clinical material and in reported series of cases, two types stand out—one that is due to hyperbilirubinemia or Rh incompatibility (kernicterus, see below) and the other due to hypoxic-ischemic encephalopathy. With control of neonatal hyperbilirubinemia (by use of anti-Rh immune globulin, exchange transfusions, and phototherapy), kernicterus has almost disappeared, whereas the other, more severe hypoxic-ischemic form regularly continues to be seen. Rarely, a congenital, nonhemolytic icterus or a glucose-6-phosphate dehydrogenase deficiency produces the same syndrome.

Like the spastic states, double athetosis may not be recognized at birth but only after several months or a year has elapsed. In some cases the appearance of choreoathetosis is for unexplained reasons delayed for several years; it may seem to progress during adolescence and even early adult life. It must then be differentiated from some of the inherited metabolic and degenerative extrapyramidal diseases. Chorea and athetosis dominate the clinical picture, but bewildering combinations of involuntary movements—including dystonia, ataxic tremor, myoclonus, and even hemibalismus—may be found in a single case. At times, we have been unable to classify the movement disorder because of its complexity. It should be noted that practically all instances of double athetosis are also associated with a defect in voluntary movement.

Choreoathetosis in infants and children varies greatly in severity. In some, the abnormal movements are so mild as to be misinterpreted as restlessness or “the fidgets”; in others, every attempted voluntary act provokes violent involuntary spasms, leaving the patient nearly helpless. The clinical features of choreoathetosis and other involuntary movements is discussed in Chap. 4.

An early hypotonia, followed by retardation of motor development, is the rule in these cases. Erect posture and walking may be delayed until the age of 3 to 5 years and may never be attained in some patients. Tonic neck reflexes or fragments thereof tend to persist well beyond their usual time of disappearance. The plantar reflexes are usually flexor, though they may be difficult to interpret because of the continuous flexion and extension of the toes. Sensory abnormalities are not found. Because of the motor and speech impairment, patients are often erroneously thought to be mentally defective. In some, this conclusion is doubtless correct, but in others intellectual function is adequate, and a few are educable to a high level.

A variety of rehabilitative measures have been tried: physiotherapy, surgery, sensory integrative therapy, progressive patterned movement, and neuromuscular facilitation. We agree with Hur, who has critically reviewed this subject, that properly controlled studies provide no proof of the success of any of these measures. Surely, with growth and development, new postures and motor capacities are acquired. The less severely affected patients can even make successful occupational adjustments. The more severely affected ones rarely achieve a degree of motor control that permits them to live independently. One sees some of these unfortunate persons bobbing and twisting laboriously as they make their way in public places.

Imaging studies are seldom of diagnostic value. Mild cerebral atrophy and loss of volume of the basal ganglia are seen in some cases, and cavitory lesions are present in some of the severe anoxic encephalopathies. The EEG is rarely helpful unless there are seizures.

The most frequent pathologic finding in the brain has been a whitish, marble-like appearance of the putamen, thalamus, and border zones of the cerebral cortex. These whitish strands represent foci of nerve cell loss and gliosis with condensation of bands of transversing myelinated fibers—so-called status marmoratus (état marbré). This lesion does not develop if the insult occurs after infancy, i.e., after the myelination glia have completed their developmental cycle.

**Kernicterus** This is now a rare cause of extrapyramidal motor disorder in children and adults. Such cases are the neurologic sequelae of erythroblastosis fetalis secondary to Rh and ABO blood incompatibilities or to a deficiency of the hepatic enzyme glucuronosyltransferase. The symptoms of kernicterus appear in the jaundiced neonate on the second or third postnatal day. The infant becomes listless, sucks poorly, develops respiratory difficulties as well as opisthotonus (head retraction), and becomes stuporous as jaundice intensifies. The serum bilirubin is usually greater than 25 mg/dL. In acidotic and hypoxic infants (e.g., those with low birth weight and hyaline membrane disease), the kernicteric lesions develop with much lower levels of serum bilirubin.

The majority of infants with this disease die within the first week or two of life. Many of those who survive are mentally retarded, deaf, hyponictonic, totally unable to sit, stand, or walk, and spend their lives in homes for the feebleminded. There are exceptional patients, however, obviously less damaged, who are mentally normal or at most only slightly limited. These are the ones who develop a variety of persistent neurologic sequelae—choreoathetosis, dystonia, and rigidity of the limbs—a picture not too different from that of cerebral spastic diplegia with involuntary movements. Kernicterus should always be suspected if an extrapyramidal syndrome is accompanied by bilateral deafness and paralysis of upward gaze. Later there may be a greenish pigmentation of the dental enamel.

Neonates who die in the acute postnatal stage of kernicterus show a unique yellow staining (icterus) of nuclear masses (at one time called the “Kern nuclei”) in the basal ganglia, brainstem, and cerebellum. In those surviving this postnatal insult, the pathologic changes consist of a symmetrically distributed nerve cell loss and gliosis in the subthalamic nucleus of Luys, the globus pallidus, the thalamus, and the oculomotor and cochlear nuclei; these lesions are the result of the hyperbilirubinemia. In more than 30 cases examined by R. D. Adams, the immature cerebral cortex including the hippocampus was spared. In the newborn, unconjugated bilirubin can pass through the poorly developed blood-brain barrier into these nuclei, where it is assumed to be directly toxic. Acidosis and hypoxia exacerbate the effect. Also in the newborn, the development of hyperbilirubinemia is enhanced by a transient deficiency of the enzyme glucuronosyltransferase, essential for the conjugation of bilirubin. **Hereditary hyperbilirubinemia**, due to lack of this enzyme (Crigler-Najjar syndrome), may exhibit the same effects on the nervous system at a later period of infancy or childhood as hyperbilirubinemia due to Rh incompatibility.

Immunization, phototherapy, and exchange transfusions designed to prevent high levels of unconjugated serum bilirubin have been shown to protect the nervous system. If the blood bilirubin level can be held to less than 20 mg/dL (10 mg/dL in prematures),
the nervous system may escape postnatal damage. The effective use of these measures has practically eradicated this dreaded disease.

Both kernicterus and ischemic état marbré must be differentiated clinically from hereditary choreoathetosis, the Lesch-Nyhan syndrome, and—later in life—from ataxia-telangiectasia and Friedreich ataxia.

**Congenital and Neonatal Ataxias** In these patients, difficulty in standing and walking cannot be attributed to spasticity or paralysis. Again, hypotonia and poverty of movement are the initial motor abnormalities; the cerebellar deficit becomes manifest only later, when the patient begins to sit, stand, and walk. There may or may not be a delay in reaching the normal “motor milestones.” Attempts to attain sitting balance will first reveal an unsteadiness that is not soon overcome, even with practice. Reaching for a proffered toy is accomplished by jerky, incoordinated movements. The first steps are unsteady, as would be expected, with many tumbles, but the gait remains clumsy. Instability of the trunk may be accompanied by similar, more or less rhythmic bobbing movements of the head, so-called titutation. Despite the severity of the ataxia, the muscles are of normal size, and voluntary movements, though weak in some patients, are possible in all the limbs. The tendon reflexes are present, and the plantar reflexes are either flexor or extensor. In some cases, the ataxia is later associated with spasticity rather than hypotonia (spastic-ataxic diplegia). Relative improvement may occur in later years. In the older child, a cerebellar gait, ataxia of limb movements, nystagmus, and uneven articulation of words are readily distinguished from myoclonus, chorea, athetosis, dystonia, and tremor. We have seen cases of a cerebellar-like tremor in adults that had been attributed to neonatal injury; the MRI did not show cerebellar atrophy.

In only a few cases have the pathologic changes been studied. Aplasia or hypoplasia of the cerebellum has been observed, but sclerotic lesions of the cerebellum are more common. The CT scan or MRI verifies the cerebellar atrophy. A cerebral and cerebellar lesion may coexist in patients with congenital ataxia, which is the reason for the term cerebrocerebellar diplegia.

Several risk factors have been identified in the congenital ataxias. Most importantly, cerebellar ataxia may be the most prominent or sole effect of neonatal ischemia-hypoxia. A genetic factor is operative in some cases (Hagberg and Hagberg). Radiation of the maternal abdomen during the first trimester of pregnancy is said to have resulted in cerebellar hypoplasia. Mercury poisoning in utero is another cause of congenital ataxia. Many cases remain unexplained in our experience.

**Pontocerebellar Hypoplasias** Aside from the congenital ataxia described above, there are several rare familial forms in which a failure of cerebellar development is associated with mental retardation. Joubert reported a family in which there was dysgenesis of the vermis of the cerebellum; mental retardation; episodic hyperpnea; irregular, jerky eye movements; and unsteady gait. The syndrome appeared in four of six siblings. In other reports, choroidal-retinal colobomas, polydactyly, cryptorchidism, and cryptorchidism have been mentioned. Detailed examination of the cerebra of such individuals has been lacking. In the Gillespie syndrome, a combination of aniridia, cerebellar ataxia, and mental retardation are the dominating features. In the Paine syndrome, a familial disorder with developmental delay and mental retardation, there is microcephaly, spasticity, optic hypoplasia, and myoclonic ataxia, the last presumably related to the cerebellar hypoplasia. These dysgeneses and the disequilibrium syndrome reported from Sweden are unified by the cerebellar ataxia; in the past, they fell into the group of ataxic cerebellar palsies. Imaging studies demonstrate the cerebellocerebral abnormality. Genetic factors are operative in some, but matters pertaining to etiology remain obscure (see Harding for details). One form of a pure congenital cerebellar hypoplasia has been mapped to a gene locus on chromosome Xq. The ataxia was inherited as an X-linked recessive trait and was nonprogressive beyond early childhood.

**Differential Diagnosis of the Congenital Ataxias** The congenital ataxias must be distinguished from the progressive hereditary ataxias. The latter are likely to begin at a later age than the congenital ones. Some hereditary ataxias are intermittent or episodic, one of which is responsive to acetazolamide, as pointed out on page 827. Several forms of childhood ataxia are neither congenital nor hereditary; they have an acute onset and may persist during childhood, adolescence, and adult life.

Also to be distinguished from the ataxias of congenital and neonatal origin is an acute cerebellar ataxia of childhood, which can usually be traced to a viral infection or a postinfectious encephalitis, particularly after chickenpox. The opsoclonus-myoclonus (“dancing eyes”) syndrome of Kinsbourne is another postinfectious disease peculiar to childhood (see pages 239 and 641). The cerebellar ataxia in this disease may be overshadowed by polymyoclonus, which mars every attempted movement. With improvement, under the influence of corticosteroids, a cerebellar disorder of speech and movement becomes evident. A majority of the patients in which the disease became chronic (16 of the 26 cases followed by Marshall et al) were found later to be mentally backward. The cause of the disease has never been established. An occult neuroblastoma or other tumor is uncovered occasionally.

In the differential diagnosis of these acute forms of cerebellar ataxia, one must not overlook intoxication with phenytoin, barbiturates, or similar drugs.

**The Flaccid Paralyses and the “Floppy Infant”** (Table 38-5; See also pages 946 and 1198) The rare cerebral form of generalized flaccidity, first described by Foerster and called cerebr al atonic diplegia, has already been mentioned. It can usually be distinguished from the paralysis of spinal and peripheral nerve origin and congen-

ital muscular dystrophy by the retention of postural reflexes (flexion of the legs at the knees and hips when the infant is lifted by the axillae), preservation of tendon reflexes, and coincident failure of mental development. The Prader-Willi syndrome, discussed earlier in the chapter, also presents at first as a generalized hypotonia.

The syndrome of infantile spinal muscular atrophy (Werdnig-Hoffmann disease) is the leading example of flaccid paralysis of lower motor neuron type. Perceptive mothers may be aware of a paucity of fetal movements in utero; in most cases the motor defect becomes evident soon after birth or the infant is born with arthrogrypotic deformities. Several other types of familial progressive muscular atrophy have been described in which the onset is in early or late childhood, adolescence, or early adult life. Weakness, atrophy, and reflex loss without sensory change are the main features and are discussed in detail in Chap. 39. A few patients suspected of having infantile or childhood muscular atrophy prove, with the passage of time, to be merely inactive “slack” children, whose motor development has proceeded at a slower rate than normal. Others may remain weak throughout life, with thin musculature. These and several other congenital myopathies—central core, rod-body, nemaline, mitochondrial, myotubular, and fiber-type disproportion and predominance—are described in Chap. 52. Unlike Werdnig-Hoffmann disease, the effects of many of them tend to diminish as the natural growth of muscle proceeds. Rarely, polymyositis and acute idiopathic polynuertritis manifest themselves as a syndrome of congenital hypotonia.

Infantile muscular dystrophy and lipid and glycogen storage diseases may also produce a clinical picture of progressive atrophy and weakness of muscles. The diagnosis of glycogen storage disease (usually the Pompe form) should be suspected when progressive muscular atrophy is associated with enlargement of the tongue, heart, liver, or spleen. The motor disturbance in this condition may be related in some way to the abnormal deposits of glycogen in skeletal muscles, though it is more likely due to degeneration of anterior horn cells that are also distended with glycogen and other substances. Certain forms of muscular dystrophy (myotonic dystrophy and several types of congenital dystrophy) may also be evident at birth or soon thereafter. The latter may have led to arthrogryposis and club foot (see page 1244). All of these disorders are described in detail in the chapters on muscle diseases.

Brachial plexus palsies, well-known complications of dystocia, usually result from forcible extraction of the fetus by traction on the shoulder in a breech presentation or from traction and tipping of the head in a shoulder presentation. The effects of such injuries are sometimes lifelong. Their neonatal onset is betrayed later by the small size and inadequate osseous development of the affected limb. Either the upper brachial plexus (fifth and sixth cervical roots) or the lower brachial plexus (seventh and eighth cervical and first thoracic roots) suffer the brunt of the injury. Upper plexus injuries (Erb) are about 20 times more frequent than lower ones (Klumpke). Sometimes the entire plexus is involved (page 1164).

Facial paralysis, due to forceps injury to the facial nerve immediately distal to its exit from the stylomastoid foramen is another common (usually unilateral) peripheral nerve affection in the newborn. Failure of one eye to close and difficulty in sucking make this condition easy to recognize. It must be distinguished from the congenital facial diplegia that is often associated with abducens palsy, i.e., the Möbius syndrome discussed earlier in the chapter. In most cases of facial paralysis due to physical injury, function is recovered after a few weeks; in some, the paralysis is permanent and may account for lifelong facial asymmetry.

**Treatment** Assistive devices, stretching therapy, and conventional orthopedic measures for joint stabilization and relief of spasticity are all useful. Injection of botulinum toxin for the relief of spasticity has gained wide favor and is now used early in the child’s life to pre-empt deformities. Most published trials have been too small, however, to allow firm conclusions to be drawn about the durability of this treatment. Finally, hyperbaric oxygen treatment of children with cerebral palsy was not effective in a randomized trial conducted by Collet and colleagues, despite periodic claims to the contrary.

In summary, it can be said that all these forms of disabling motor abnormalities rank high as important issues in neuropediatrics. In attempts at prevention, steps have been taken in most hospitals to identify and eliminate risk factors. Indeed, better prenatal care, reduction in premature births, and control of respiratory problems in critical care wards have reduced their incidence and prevalence. Physical and mental therapeutic measures appear to be helpful, but many of the methods have been difficult to evaluate in a nervous system undergoing maturation and development. The neurologist can contribute most by segregating groups of cases of identical pattern and etiology and in differentiating the congenital groups of delayed expressivity from the treatable acquired diseases of this age period. Woefully lacking are critical neuropathologic studies.

**INTRAUTERINE AND NEONATAL INFECTIONS**

Throughout the intrauterine period the embryo and fetus are subject to particular infections. Since the infective agent must reach the fetus through the placenta, it is evident that the permeability of the latter at different stages of gestation and the immune status of the maternal organism are determinative. We include a discussion of these intrauterine infections here because some of them may lead to malformations or destructive lesions of the brain and, later in life, must be distinguished from developmental abnormalities.

Until the third to fourth month of gestation, the large microbial organisms—such as bacteria, spirochetes, protozoa, and fungi—cannot invade the embryo, even though the mother harbors the infection. Viruses may do so, however—specifically rubella, cytomegalovirus (CMV), human immunodeficiency virus (HIV), and possibly others. The rubella virus enters embryonal tissues during the first trimester, *Treponema pallidum* in the fourth or fifth postconceptional months, and *Toxoplasma* after that period. Bacterial meningitis (except for that due to *Listeria monocytogenes*, described below) is essentially a paranatal infection contracted during or immediately after parturition. Neonatal herpes simplex encephalitis, due to the type 2 (genital) virus, is also usually acquired by passage through an infected birth canal. Some cases of HIV infection may be acquired during delivery, but most are due to transplacental transmission.

The main neonatal infections—*toxoplasmosis, rubella, CMV, and herpes*—are commonly designated by the acronym TORCH. With the persistence of *Listeria*, the rise of AIDS infections, and a marked reduction in rubella infections, the mnemonic LATCH, which includes *Listeria* and AIDS, might be more appropriate. Infants with any of these infections share certain common features, such as low birth weight, prematurity, congenital heart disease, purpura, jaundice, anemia, microcephaly or hydrocephaly, cerebral calcifications, choriorretinitis, cataracts, microphthalmia, and pneumonia; as a corollary, if any combination of these features is man-
ifest, one should suspect one of these infectious agents and take measures to identify it. However, all these clinical manifestations are not likely to be present in any one infant, and in the cases of rubella and CMV, only a small percentage of infected infants will show major systemic signs or symptoms. Nevertheless, on clinical grounds alone, certain infections can be identified and others excluded. For example, cerebral calcifications are present mainly in toxoplasmosis and CMV encephalopathy, being rare in rubella and absent in HSV encephalitis; the calcifications are widely disseminated in toxoplasmosis and have a periventricular distribution in CMV infection. Cardiac lesions are present only with rubella, and deafness occurs only with CMV and rubella. Thus, there are clinical signposts to guide the clinician in selecting the appropriate diagnostic tests. And importantly, in considering neonatal infections, one must also search for other, less common infectious types (see Chaps. 32 and 33).

Added difficulty in the diagnosis of embryonal and fetal infections arises when the mother has been entirely asymptomatic. Isolation of the organism from fetal and neonatal tissues is possible, but usually they are inaccessible, and it may be impossible to demonstrate antibodies or other immune responses because of the early stage of the infection or limitations of the infant’s immune response.

Rubella

Gregg, in 1941, first reported the association of maternal rubella and congenital cataracts in the neonate. His observations were quickly verified, and soon it became widely known that cataracts, deafness, congenital heart disease, and mental retardation constituted a kind of tetrad diagnostic of this disease. That a virus could affect so many tissues, causing in essence a noninflammatory developmental disorder of multiple organs, was a novel concept, and it raised the interesting prospect that other viruses might have similar effects. Surprisingly, however, only CMV and possibly HSV have been incriminated in embryonal-developmental neuropathology. A large number of other viruses (e.g., influenza, Epstein-Barr, hepatitis) have been implicated in human teratogenesis, but in none is the relationship beyond doubt.

It is now well established that most instances of congenital rubella infection occur in the first 10 weeks of gestation and that the earlier the infection occurs, the greater the risk to the fetus. However, there may be some risk beyond the first trimester, up to the 24th week, according to Hardy.

Following the experience of the massive rubella epidemics of 1964 and 1965, the congenital rubella syndrome has been expanded to include low birth weight; sensorineural deafness, sometimes unilateral (the most common complication); microphthalmia; pigmentary degeneration of the retina (salt-and-pepper chorioretinitis); glaucoma, cloudy corneas, and cataracts of special type (the latter two abnormalities usually cause visual impairment); hepatosplenomegaly, jaundice, and thrombocytopenic purpura; and patent ductus arteriosus or interventricular septal defect. There may be one, a few, or many of these abnormalities, in various combinations. The mental retardation is severe and may be accompanied by seizures and motor defects such as hemiplegia or spastic diplegia and rarely by seizures. Psychiatric symptoms, some resembling autism, are not infrequent.

Infection of the fetus after the first trimester results in a less impressive neonatal syndrome. The infant may seem lethargic and fail to thrive. The cranium is abnormally small. Only a cardiac abnormality, deafness, or chorioretinitis may provide clues to the diagnosis. The CSF later may show an increase of mononuclear cells and an elevated protein. The infection may persist for a year or longer. Foci of calcification are rare, and CT scanning and MRI are of little help in diagnosis. The maternal infection may be so mild that it is passed off as minor; but even when it is evident, the fetus is spared in about 50 percent of cases. Diagnosis can be verified in the neonate by demonstrating IgM antibodies to the virus or by the isolation of the virus from the throat, urine, stool, or CSF. Also, the virus has been obtained from cells in the amniotic fluid. In subsequent pregnancies the fetus has been normal in our experience.

The neuropathology is of considerable interest. In the nervous system of abortuses (the abortion performed because of proven maternal rubella in the first trimester), R. D. Adams found no visible lesions by light microscopy, even though the virus had been isolated from the brain by Enders. At this period of development there is no inflammatory reaction because of the absence of polymorphonuclear leukocytes, lymphocytes, and other mononuclear cells in the fetus. At birth the brain is usually of normal size, and there may be no discernible lesions. In a few, a mild meningeal infiltration of lymphocytes as well as a few zones of necrosis and vasculitis with later calcification of vessels are seen, as are small hemorrhages, presumably related to the thrombocytopenia. Smallness of the brain and delay in myelination have been observed in children dying at 1 to 2 years of age. None of the brains in our series have been malformed. Rubella virus continues to be recoverable from the CSF for at least 18 months after birth. A delayed progressive rubella encephalitis in childhood is also known and is described on page 651. Our colleagues have had two cases, studied in serial sections by Yakovlev, that survived 5 to 6 years.

Since there is no treatment for the active infection, the obvious approach to the problem of congenital rubella infection is to make sure that every woman has been vaccinated against rubella or has antibodies as a result of infection prior to pregnancy. The widespread use of rubella vaccine has reduced the chance of major outbreaks, but sporadic infections continue to be seen, and outbreaks of epidemic proportions continue to occur in developing countries.

Congenital Cytomegalovirus Infection

For many years it was known that in the tissues of some infants who died in the first weeks and months of life there were swollen cells containing intranuclear and cytoplasmic inclusions. This cytologic change seemed related to the fatalities. In 1956 and 1957, three different laboratories isolated what has come to be called the human cytomegalovirus (see Weller). This has proved to be the most frequent intrauterine viral infection, rivaled in the current era only by HIV.

CMV disease is caused by a DNA virus, a member of the herpes group, and is widespread in the general population. Although cervicitis is common, the virus is probably transmitted to the fetus transplacentally. Infection of the fetus usually occurs in the first trimester of pregnancy, sometimes later, by way of an inappropriate maternal viremia and infection of the placenta. The newborn can also be infected in the course of delivery or afterward by the mother’s milk or by transfusions. However, only a small proportion of women known to harbor the virus give birth to infants with active infection. The likelihood of the fetus being infected is much greater if the seronegative mother becomes infected for the first time during pregnancy. Eighteen percent of infants born to
such mothers were symptomatic at birth, and 25 percent became blind, deaf, or mentally retarded within a few years (Fowler et al). In mothers with recurrent CMV infection, the infants were asymptomatic at birth, and only a few developed serious sequelae. Evidently, the presence of maternal antibodies before conception protects against congenital CMV infection.

Early infection of the fetus may result in a malformation of the cerebrum; later, there is only inflammatory necrosis in parts of the normally formed brain. In the low-birth-weight or full-term infant, the clinical picture is one of jaundice, petechiae, hematemesis, melena, direct hyperbilirubinemia, thrombocytopenia, hepatosplenomegaly, microcephaly, mental defect, and convulsions. Cells in the urine may show cytomegalic changes. There is a pleocytosis and an increased protein in the CSF. Disseminated inflammatory foci have been observed in the cerebrum, brainstem, and retinae. Here there were aggregates of lymphocytes, mononuclear cells, and plasma cells. The mononuclear histiocytes (microglial cells) contain inclusion bodies; some astrocytes are similarly affected. The granulomas later calcify, particularly in the periventricular regions. Often there is hydrocephalus.

Congenital CMV infections pose a much greater problem than rubella. There is no way of identifying the infected fetus prior to birth or to prevent inapparent infections in the pregnant woman. As indicated above, if the pregnant woman has measurable titers of antibodies to CMV at the time of conception, her infant is relatively protected. Moreover, some infected infants (with viruria) may appear normal at birth but develop neural deafness and mental retardation several years later. Viral replication in infected organs continues after the first year and health workers are at risk. A second child may be infected.

There is no known treatment. The difficulties in prenatal diagnosis of maternal infection preclude planned abortion. Routine serologic testing should be done on every young woman of childbearing age. Until an effective vaccine becomes available, pregnancy should be avoided if a sexual partner is infected.

**Congenital HIV Infection and AIDS**

In the United States, about 10 percent of cases of acquired immunodeficiency syndrome (AIDS) have occurred in women, almost all of them of childbearing age, and the rate of new cases is increasing at a faster rate among them than among men. The numbers are higher in many developing countries and particularly in parts of Africa. In children, practically all instances of AIDS come from an HIV-infected mother ("vertical transmission"). The infection may be acquired in utero, during delivery, or from breast-feeding. The relative importance of each of these modes of transmission has not been settled.

It is estimated that HIV infection and AIDS occur in 15 to 30 percent of infants born to HIV-seropositive mothers (see Prober and Gerson). Infected infants present special difficulties in diagnosis, and the infection runs a more accelerated course in them than in adults. In the perinatal period, infected and noninfected infants can only rarely be distinguished clinically, and laboratory diagnosis is hampered by the presence of maternally derived antibody to HIV. The initial clinical signs usually appear within a few months after birth; practically all infected infants become ill before their first birthday, and very few are asymptomatic beyond 3 years of age. Early signs consist of lymphadenopathy, splenomegaly, hepatomegaly, failure to thrive, oral candidiasis, and parotitis. In the European Collaborative Study, comprising 600 children born to HIV-infected mothers, 83 percent of infected children showed laboratory or clinical features of HIV infection by 6 months of age. By 12 months, 26 percent had clinical symptoms of AIDS and 17 percent had died of HIV-related diseases. Once AIDS is established in children, it does not differ materially from the syndrome in adults (Chap. 33).

There is often a delay in the attainment of psychomotor milestones. In others, after a period of normal development, a psychomotor decline begins, with corticospinal or peripheral nerve signs, often with pleocytosis in the CSF. The typical giant-cell AIDS encephalitis, neuritis, and myelitis is easily distinguished from CMV encephalitis and toxoplasmosis.

Infected children are also subject to a variety of opportunistic infections, including bacterial meningitis, toxoplasmosis, CMV encephalitis, fungal infections (cryptococcosis, aspergillosis, candidiasis), herpes simplex, syphilis, zoster, and mycobacterial meningitis. There may also be vascular lesions, with infarction or hemorrhage and lymphoid neoplasia. These are discussed in Chaps. 32 and 33. To date there is little that one can do for these children, but this may be changing with the current use of three-drug anti-retroviral therapy, as described in Chap. 33.

**Congenital Toxoplasmosis**

This tiny protozoan *Toxoplasma gondii*, occurring freely or in pseudocyst form, is a frequent cause of meningoencephalitis in utero or in the perinatal period of life. The disease exists in all parts of the United States but is more frequent in western European countries, particularly in those with hot, humid climates. The mother is most often infected by exposure to cat feces, handling uncooked infected mutton or other meat, or eating partially cooked meat, but she is nearly always asymptomatic or has only a mild fever and cervical lymphadenopathy.

The precise times of placental and fetal invasion are not known, but presumably they occur late in the gestational period. The clinical syndrome usually becomes manifest in the first days and weeks of postnatal life, when seizures, impaired alertness, hypotonia, weakness of the extremities, progressive hydrocephalus, and chorioretinitis appear. The retinal lesions consist of large pale areas of destroyed retina surrounded by deposits of pigment. If the infection is severe, the maculae are destroyed; optic atrophy and microphthalmos follow. In older infants, we have several times observed hemiplegias, first on one side and then on the other, followed by tension hydrocephalus. The latter is present in about one-third of the cases. The CSF contains a moderate number of white blood cells, mostly lymphocytes and mononuclear cells, and the protein content is in the range of 100 to 400 mg/dL (i.e., a higher protein content than all other neonatal infections except bacterial meningitis). The glucose values are normal. Less than 10 percent of infected children recover; the others are mentally retarded, with seizures and paralysis. In those without symptoms of infection at birth, the outcome is better.

Granulomatous masses and zones of inflammatory necrosis about the ependyma and meninges. The organisms, 6 to 7 mm in length and 2 to 4 mm in width, are visible in and near the lesions. Microcysts may also be found, lying free in the tissues without surrounding inflammatory reaction. The necrotic lesions calcify rapidly and, after several weeks or months, are readily visible in plain films of the skull. These appear in periventricular and other regions of the brain as multiple nodular densities.

In adults, often in association with AIDS, the disease takes
the form of a rapidly evolving meningitis and multifocal encephalitis in conjunction with myocarditis, hepatitis, and polyomyositis. This syndrome is described on page 623, as are the diagnostic tests and treatment. In the infant, infections such as rubella, syphilis, CMV disease, and herpes simplex must be considered in the differential diagnosis. The most reliable means of diagnosis is the IgM indirect fluorescent antibody test, performed on umbilical cord blood. Passive transfer of IgG antibody from mother to fetus takes place, but its presence in the latter is not proof of active infection.

In women who develop antibodies in the first 2 or 3 months of pregnancy, treatment with spiramycin (Rovamycin) prevents fetal infection. Once the fetus is infected, pyrimethamine and sulfadiazine must be used. A later second pregnancy is not affected.

**Congenital Neurosyphilis**

The clinical syndromes and pathologic reactions of congenital neurosyphilis of the newborn are similar to those of the adult, as described on pages 614 to 618. Such differences as exist are determined principally by the immaturity of the nervous system at the time of spirochetal invasion.

The syphilitic infection may be transmitted to the fetus at any time from the fourth to the seventh months. The fetus may die, with resulting miscarriage or stillbirth, or may survive only to be born with florid manifestations of secondary syphilis. The dissemination of the spirochetes throughout the body, the time of appearance of the secondary manifestations, and the time of formation of anti-syphilitic antibodies (reagin) in the blood are all governed by the same biologic principles that apply to adult syphilis.

At birth the spirochtemia may not have had time to cause syphilitic antibodies to appear; hence a negative Venereal Disease Research Laboratory (VDRL) reaction in umbilical cord blood does not exclude syphilis. In unselected groups of syphilitic mothers, 25 to 80 percent of fetuses are infected, and in 20 to 40 percent of those infected, the CNS is invaded, as judged by the finding of abnormal CSF. The types of congenital neurosyphilis (asymptomatic and symptomatic meningitis, meningovascular disease, hydrocephalus, general paresis, and tabes dorsalis) are the same as those in the adult except for the great rarity of tabes dorsalis. The classic Hutchinson triad (dental deformities, interstitial keratitis, and bilateral deafness) is infrequently observed in complete form. The sequence of neurologic syndromes is also the same as in the adult, all stemming basically from a chronic spirochetal meningitis. The infection may become symptomatic in the first weeks and months of postnatal life, meningovascular lesions and hydrocephalus reaching maximal frequency during the period from 9 months to 6 years. An early form of syphilitic meningoencephalitis may occur at 1 to 2 years and result in severe mental retardation. More often, a congenital paresis and tabes usually appear between the ninth and fifteenth years. The pathologic basis of the neurosyphilitic syndromes are discussed on page 614.

All neurologists observe fewer and fewer cases of congenital neurosyphilis as the years pass, but there may be a recrudescence of the disease in HIV-infected patients. If the syphilitic mother is treated before the fourth month of pregnancy, the fetus will not be infected. The affected infant may be normal at birth or exhibit only mucocutaneous lesions, hepatosplenoemegaly, lymphadenopathy, and anemia. There are in the neonatal period no signs of meningeal invasion, or there may be only an asymptomatic meningitis. If the latter is actively treated until the CSF is normal, vascular lesions of brain and spinal cord, hydrocephalus, general paresis, and tabes dorsalis will not develop. If cases of meningovascular syphilis, general paresis, and tabes dorsalis are treated for 3 to 4 weeks with penicillin until the CSF is rendered acellular and the protein reduced to normal, the neurologic disorder will be arrested and there is often functional improvement.

Congenital syphilis must be considered a potential albeit rare cause of epilepsy and mental retardation. Once the syphilitic infection has been treated in early life and rendered inactive (acellular CSF, normal protein), the occurrence of a congenital luetic infection can only be substantiated by an accurate history; the finding of the syphilitic stigmata in the eyes, teeth, and ears; or a positive serologic reaction in the CSF.

Treatment of syphilis in the child follows along the same lines as treatment of the syphilitic adult (page 618), with appropriate adjustment of dosage in accordance with the child’s weight.

**Other Viral and Bacterial Infections**

Several other infections of late fetal life or the neonatal period are only mentioned here, for to describe them all would be tedious and would elucidate no new neurologic principles. Meningitis due to the small gram-positive rod *Listeria monocytogenes* may be acquired in the usual way, at the time of passage through an infected birth canal or in utero, as a complication of maternal and fetal septicemia due to this organism. In the latter case, it causes abortion or premature delivery. Neonatal bacterial meningitis is a particularly devastating and often fatal type of bacterial infection, not easily diagnosed unless the pediatrician is alert to the possibility of a silent meningitis in every case of neonatal infection (page 596).

Herpes simplex virus (HSV) encephalitis may destroy large parts of the infant brain, particularly of the temporal lobes, and is frequently fatal. Coxsackie B, polioviruses, other enteroviruses, and arboviruses (western equine) seem to be able to cross the placental barrier late in pregnancy and cause encephalitis or encephalomyelitis in the near-term fetus. It is indistinguishable from the disease in the very young infant.

Herpes zoster may occur in utero, leaving cutaneous scars and retarding development. Or zoster may appear soon after birth, the infection having been contracted from the mother. Only later in childhood can varicella induce an autoimmune perivenous demyelination and possibly a direct infection, affecting predominantly the cerebellum (pages 641 and 790), or the now rare Reye syndrome.

Epstein-Barr virus is another not infrequent cause of meningoencephalitis. In some instances it may present as an aseptic meningitis or a Guillain-Barré type of acute polyneuritis. This infection tends to affect the nervous system of children rather than that of adults, but there are exceptions to this comment. It is estimated that approximately 2 percent of children and adolescents with this infection have some type of neurologic dysfunction; rarely will this be the only manifestation of the disease. Stupor, chorea, and aseptic meningitis were the main neurologic findings in the case reported by Friedland and Yahr, and acute cerebellar ataxia and deafness were observed in the case of Erzurum and associates (see also Chaps. 32 and 33).

**Epilepsies of Infancy and Childhood**

The major types of seizure disorder have already been discussed in some detail in Chap. 16. In bringing them up here, attention is again drawn to the fact that epilepsy is mainly a disease of infancy.
and childhood. Approximately 75 percent of epileptics fall into these age periods, and some of the most interesting and unique types of seizure are peculiar to these epochs of life. Epilepsies that are observed exclusively in infants and children are benign neonatal convulsions, benign myoclonic epilepsy of infancy, febrile seizures (both genetic and acquired), infantile spasms of West, absence seizures, the Lennox-Gastaut syndrome, rolandic and occipital paroxysms and other benign focal epilepsies, and the juvenile myoclonic epilepsies.

One principle that emerges is that the form taken by seizures in early life is in part age-linked. Neonatal seizures are predominantly partial or focal; infantile seizures take the form of myoclonic flexor (sometimes extensor) spasms; and the various forms of petit mal are essentially diseases of childhood (4 to 13 years). The motor phenomena of epilepsy in young children are often termed myoclonic, but this should not be confused with other, later-occurring epilepsies that are endowed with the same name. Further, certain epileptic states tend to occur only during certain epochs of life—one type of febrile seizures from 6 months to 6 years, generalized or temporal spike-wave activity with benign motor and complex partial seizures from 6 to 16 years, and juvenile myoclonic epilepsy in the mid- and late-adolescent years. In general, idiopathic epilepsy, so called because the cause cannot be determined, is predominantly a pediatric neurologic problem. This is not to say that seizures of unknown cause do not occur for the first time in adult life but rather that the onset of such seizures is far more frequent in childhood and tends to diminish once adulthood is reached.

The clinical characteristics of infantile and childhood seizures, including those of genetic origin, are fully described in Chap. 16.

SEVERE FORMS OF MENTAL RETARDATION

The subject of mental retardation was introduced in Chap. 28, where it was pointed out that two major categories of this disorder have been delineated. In one, and by far the more common group, the mental retardation is relatively mild, allowing the individual to benefit from training and education; it is often familial and is featured by a lack of definite neurologic abnormalities (except possibly a slightly higher incidence of seizures) and the absence of neuropathologic changes. A large part of this group, falling between 2 and 3 standard deviations below the normal mean IQ, probably are the lower end of the Gaussian curve of intelligence, the converse of which is genius. This group is, however, contaminated with a small number of defined diseases of the nervous system occurring in a less severe form, as was pointed out on page 513. In a second group, the degree of mental retardation is usually more severe (IQ of 50 to 70), and yet more so in the third group (IQ less than 50). Most of the cases in the second and third groups are nonfamilial, and a wide variety of neuropathologic changes are in evidence. The subdivisions are not absolute, for there are a few metabolic and developmental diseases in which mental retardation is profound yet with no somatic or neurologic abnormalities and, most importantly, well-defined neuropathologic changes are lacking. Here we refer to conditions such as Rett syndrome, autism, and the X-linked mental retardation syndromes (Renpenning and fragile-X types). In this chapter only these major types of severe mental retardation are described.

The overall frequency of severe mental retardation cannot be stated precisely. Rough estimates place the figure at 0.2 to 0.4 percent of the general population and at about 10 percent of the general retarded segment of society. It is important to emphasize that in a large proportion of individuals with severe mental retardation, a particular congenital abnormality or anomaly of development cannot at present be traced to any of the disorders reviewed in the preceding pages. More precisely stated, when groups of such severely retarded patients are studied clinically, a reasonably accurate etiologic determination of the underlying brain disease can be made in only slightly more than half. According to Penrose, chromosomal abnormalities account for 15 percent, single-gene disorders for 7 percent, and environmental agents for 20 percent. Recent studies of the subtelomeric parts of chromosomes reportedly find abnormalities in another 7 percent of severely retarded children (Knight et al). No cause is found for the remaining cases. Males outnumber females 3 to 1. For purposes of comparison, our figures, obtained from a study of 1372 patients at the Walter E. Fernald School in the 1970s, are presented in Table 38-6.

From the neuropathologic standpoint, the examination of the brains of the severely retarded by conventional histopathologic methods discloses lesions in approximately 90 percent, and in fully three-quarters an etiologic diagnosis can be determined or tentatively assigned. Many of the remaining 10 percent of the “pathologically retarded” actually lack definite pathologic changes, but their brains are lighter in weight by 10 to 15 percent than age-matched normal brains. Interestingly, the proportion of vascular, hypoxic-ischemic, metabolic, and genetic lesions in this group of severely retarded individuals is much the same as is found in a group selected on the basis of “cerebral palsy.”

Here it is important to repeat a point made earlier and in Chap. 28, that a few of the severely disabled and a large majority of the mildly retarded do not have a recognizable cerebral pathology or exhibit any of the familiar and conventional signs of cerebral disease. Although the milder forms of mental retardation tend to be familial, this does not by itself separate them from the severe forms of mental retardation. There are several types of hereditary mental

Table 38-6
Causes of severe and mild mental retardation in 1372 patients at the W. E. Fernald State School
Clinical Characteristics of the Severely Retarded

These cases can be broadly divided into four groups. In one large group, designated dysmorphic retardation, a variety of physical deformities, including microcephaly, is commonly present. In a second group, with multiple system retardation, the mental backwardness is linked to nonskeletal abnormalities (e.g., hepatosplenomegaly, hematologic and skin disorders), which provide reliable clues to the underlying somatic disease. In a third group, neurologic retardation, somatic abnormalities are lacking but a configuration of neurologic signs leads to the diagnosis. In the fourth group, and the most difficult one to clarify, that comprising uncomplicated retardation, there are no (or minimal) somatic, visceral, or neurologic abnormalities. One is then forced to turn to special features of the mental retardation itself for identification of the underlying disease. Table 38-7 elaborates our classification of the types of mental retardation.

The profoundly retarded infant with a virtually unt敷able IQ is identified early in life because he does not sit, stand, or walk. If any one of these motor activities is acquired, it appears late and is imperfectly performed. Language never develops; at most a few spoken words or phrases are understood and fewer are uttered, or the patient only vocalizes in a meaningless way. Such a person may not even indicate bodily needs for food, drink, excretion, and so on. Usually the patient is continuously idle and interacts little with people and objects. Only the most primitive emotional reactions are exhibited, often without connection to an appropriate stimulus. Physical growth is usually retarded, nutrition may be poor, and susceptibility to infections is increased. Sphincteric control may never be attained, and if attained, is precarious.

When the mental defect is less severe than described above, falling into the IQ ranges of 20 to 45, or 45 to 70, there may be somatic neurologic abnormalities. If specific motor defects do not coexist, then sitting, standing, and walking are achieved but not at the expected times. The existence of a mental defect is most clearly

Table 38-7

Types of severe mental retardation

I. Dysmorphic defect with somatic developmental abnormalities in nonnervous structures
   A. Those affecting cranioskeletal structures
      1. Microcephaly
      2. Macrocephaly
      3. Hydrocephalus (including myelomeningocele with Chiari malformation and associated cerebral anomalies)
      4. Down syndrome
      5. Cretinism (congenital hypothyroidism)
      6. Mucopolysaccharidoses (Hurler, Hunter, and Sanfilippo types)
      7. Acrocephalosyndactyly (craniostenosis) and other craniosomatic abnormalities
      8. Arthrogryposis multiplex congenita (in certain cases)
      9. Dwarfism, short stature: Russel-Silver dwarf, Seckel bird-headed dwarf, Rubinstein-Taybi dwarf, Cockayne-Neel dwarf, etc.
   B. Those affecting nonskeletal structures
      1. Neurocutaneous syndromes: tuberous sclerosis, Sturge-Weber, neurofibromatosis
      2. Congenital rubella syndrome (deafness, blindness, congenital heart disease, small stature)
      3. Chromosomal disorders: Down syndrome, some cases of Klinefelter syndrome (XXY), XYY, Turner (XO) syndrome (occasionally), and others
      4. Laurence-Moon-Biedl syndrome (retinitis pigmentosa, obesity, polydactyly)
      5. Eye disorders: toxoplasmosis (chorioretinitis), galactosemia (cataract), congenital rubella
      6. Prader-Willi syndrome (obesity, hypogenitalism)
   II. Nondysmorphic mental defect without somatic abnormalities but with cerebral and other neurologic abnormalities
      A. Cerebral spastic diplegia
      B. Cerebral hemiplegia, unilateral or bilateral
      C. Congenital choreoathetosis or ataxia
         1. Kernicterus
         2. Status marmoratus
      D. Congenital ataxia
      E. Congenital atonic diplegia
      F. Syndromes resulting from hypoglycemia, trauma, meningitis, and encephalitis
      G. Associated with other neuromuscular abnormalities (muscular dystrophy, cerebellar ataxia, etc.)
      H. Cerebral degenerative diseases (lipidoses)
         1. Associated with inborn errors of metabolism (phenylketonuria, other aminoacidurias, organic acidurias, Lesch-Nyhan syndrome)
         2. Congenital infections (some cases of congenital syphilis, cytomegalic inclusion disease)
      III. Genetic mental defect of indeterminate type with minor or no signs of somatic abnormality or neurologic disorder
         A. Infantile autism, Renpenning, Williams, fragile X, Partington, and Rett syndromes
evidenced by a delay in psychomotor development and a failure to 
speak by the second or third postnatal year. The patient does not 
acquire the usual household and play activities as well as other 
children. However, delay in speech development must not, by it-
self, be taken as a mark of mental retardation, for in some children 
a unique delay in speech can be an isolated abnormality (see Chap. 
28), with subsequent normal development of speech and mental 
ability. Toilet training may be difficult to accomplish in the retarded 
child, but, again, bed-wetting may be a problem in an otherwise 
normal child. Also, the deaf child may have to be considered sepa-
rate; here the problem becomes apparent by an indifference to 
noise and reduced vocalization (stereotypy of babbling).

More searching analyses of cognitive functions in the mod-
erately retarded child have been undertaken by O’Connor and Her-
melin, by Pulsifer, and by others. These authors have measured 
efficiency of visual and auditory perception, adequacy of commu-
nication, relations between language development and thought, 
cross-modal sensory encoding, alertness, attention, and memory. It 
was concluded that none of these functions was specifically im-
paired. Instead, the retarded child could not properly encode new 
information because the memory systems and the stock of past 
asimilated knowledge were insufficient to provide a framework of 
items and categories with which new information could be inte-
grated. Some patients also seemed unable, perhaps because of this, 
to extract from perceived material selective features that could be 
translated. Further, they were unable to deal with an array of sen-
sory experiences like normal children. The complexity of these 
mental operations, which we would reduce to a global failure of 
the normal processes of apperception and integration, has been 
called by Piaget a failure of assimilation and accommodation. This 
type of inadequacy is common to many different diseases, but in 
each there are almost certainly other subtle differences that are just 
now being analyzed by neuropsychologists.

However, within the spectrum of mental retardation, apart 
from cognitive impairments, there are curious differences in be-
havior and personality, even in those with more or less the same 
IQ. Some individuals with moderately severe retardation are pleas-
ant and amiable and achieve a rather satisfactory social adjustment. 
This is particularly notable in patients with Down and Williams 
syndromes. At the opposite end of the behavioral scale are the 
syndromes of autism and that of Smith-Magenis and of DeLange, 
in which the individual fails to manifest normal interpersonal social 
contact, including communicative language. The phenylketonuric 
child is usually irritable, unaffectionate, and implacable, and the 
same is said of certain other forms of retardation, such as those 
with the DeLange syndrome, discussed earlier in the section on 
retardation with dwarfism.

Regarding differences in activity levels, many retarded indi-
viduals are slow, clumsy, and relatively akinetic. Others, as many 
as half, display an incessant hyperactivity characterized by a rest-
less, seemingly inquisitive searching of the environment. When 
thwarted, they may exhibit a low frustration tolerance. They may 
be destructive and recklessly fearless and impervious to the risk of 
injury. Some exhibit a peculiar anhedonia that renders them indif-
terent to both punishment and reward. Other aberrant types of 
behavior, such as violent aggressiveness and self-mutilation, are com-
mon.

Rhythmic rocking, head-banging, incessant arm move-
ments—so-called rhythmatias or movement stereotypies—are ob-
served in the majority of those who are severely and moderately 
severely retarded. These movements are maintained hour after hour 
without fatigue and may be accompanied by breathing sounds, 
squeals, and other exclamations. A number of them tend to be 
particularly common in certain forms of retardation: hand-flapping 
in autism, hand-wringing in Rett syndrome, and hand-waving in 
Down syndrome and other disorders. Self-stimulation, even hurt-
ful—such as striking the forehead or ears or biting the fingers and 
forearms—seems to be compulsive or perhaps to provide some sort 
of satisfaction. It is not that these rhythms are by themselves 
abnormal, for some of them occur for brief periods in normal ba-
bies, but that they persist. Nevertheless, many moderately retarded 
persons, when assigned to a simple task such as putting envelopes 
in a box, can continue this activity under supervision for several 
hours.

In the least severe types of retardation, all the mental activities 
are intact but subnormal. The point to be made is that all aspects 
of intellectual life, personality, and deportment are affected in 
slightly but differing degrees and that these effects have a neuro-
logic basis. There is more than a hint that in particular diseases, 
because of their anatomy, the cognitive experience, affective life, 
and behavior are affected in special ways.

The group of moderately retarded, like the severely retarded, 
is divisible into groups with somatic systemic and neurologic ab-
normalities, though the proportions are not the same. There are 
fewer of the dysmorphic type and more of the nondysmorphic, 
nonneurologic group.

**Etiology of Severe Mental Retardation**

From Table 38-1 it is obvious that many diseases can blight the development and 
maturational brain, leaving it in an arrested state. Some of these 
are acquired and some are congenital and hereditary. Some affect 
all parts of the organism, giving rise to associated dermal, skeletal, 
and visceral abnormalities, while others affect only the nervous 
system in particular patterns. With respect especially to the milder 
degrees of mental retardation, in all populations thus far studied, 
as mentioned above, infants of extremely low birth weight are more 
likely to have disabilities, brain abnormalities, and poorer language 
development and scholastic achievement. Mild mental retardation 
also tends to correlate with lower social status, which must relate 
in some manner to biological factors, as pointed out in the Scottish 
Low-Birth-Weight Study. Viral and spirochetal infections and par-
turitional accidents are other common causes. They act acutely and 
are theoretically preventable.

The factor of malnutrition during the fetal or infantile period 
of life as a cause of severe mental retardation has received consid-
erable attention because it is a worldwide problem. Animal exper-
iments by Winick and others have demonstrated that severe under-
nutrition in early life leads to behavioral abnormalities and 
biochemical and morphologic changes in the brain, which may be 
permanent (see Chap. 41). Galler studied a group of infants in 
Barbados who were severely malnourished during the first year of 
life and then given an adequate diet. These children were followed 
to adulthood and compared with normally nourished siblings. 
Galler observed no effect on physical growth, but there were per-
sistent attention deficits in 60 percent of the undernourished group 
and in only 15 percent of controls. The IQ scores of the former 
were also lower. Unfortunately, genetic factors could not be com-
pletely controlled. In general, it may be said that the data showing 
mental retardation to be caused by malnutrition, while suggestive, 
are far from convincing.

Severe protein-calorie malnutrition in the first 8 months of 
life, which induces kwashiorkor, was reported to retard mental de-
of eyes, nose, lips, ears, fingers, and toes are particularly specific for somatic stigmata and neurologic signs. Abnormal deficits, one begins with a careful physical examination, searching Chaps. 23 and 28.

The effect of psychologic deprivation on cognitive development has been of interest. Following the observations that complete isolation of young female monkeys had a devastating effect on their later sexual and nurturing behavior, the idea became popular that such deprivation might cause faulty mental development in humans. Orphaned and neglected babies were found to be inactive, apathetic, and backward in comparison with those who were constantly stimulated by caring mothers. But surprisingly, when nurtured properly at a later time, these babies soon caught up with their peers. This general idea of psychologic deprivation has been the basis of many interesting educational programs for poor and neglected children. To this day, however, it has not been proven that sensory, emotional, and psychologic deprivations of a degree observed in humans are the causes of severe mental retardation or repeated scholastic failure. However, the problem is a complex one, and the arguments pro and con have been carefully elaborated by Haywood and Wachs. The controversies regarding the effects of prematurity, maternal hypertension, and eclampsia, which are often associated with neonatal cerebral pathology and retarded psychomotor development, have been mentioned earlier in this chapter.

The genetic types of severe mental retardation (Down syndrome, fragile X, Prader-Willi, etc.), including the novel type associated with subtelomeric abnormalities, have been discussed in an earlier section.

**Differentiation of Types of Retardation: Clinical Approach**

As a particular guide to the pediatrician and neurologist who must assume responsibility for the diagnosis and management of backward children harboring a wide array of diseases and maldevelopments of the nervous system, the following clinical approach is suggested. First, as already described, there is an advantage in setting aside as one large group those who are only mildly retarded from those who have been severely delayed in psychomotor development since early life. With regard to the former group, having no obvious neurologic signs or physical stigmata, one should nevertheless initiate a search for the common metabolic, chromosomal, and infective diseases. In this large group one must be sure that the their defect is a general one and not one of hearing, poor sight, or the special isolated language and attention deficits described in Chaps. 23 and 28.

For patients with moderately severe and very severe cognitive deficits, one begins with a careful physical examination, searching specifically for somatic stigmata and neurologic signs. Abnormalities of eyes, nose, lips, ears, fingers, and toes are particularly important, as are head circumference and a variety of neurologic abnormalities, as outlined in Table 38-7. Data so obtained allow classification into one of three categories, as follows:

1. **In those with somatic abnormalities** (with or without obvious neurologic signs), one assumes the presence of a maldevelopment of the brain, possibly caused by a chromosomal abnormality. The psychomotor retardation is usually severe and often nongenetic and, as a rule, has a well-defined neuro-pathology. Diagnosis is determined by the gestalt of physical signs. The possible maldevelopments are numerous and diverse and have been summarized in Tables 38-1 and 38-7; some of the main ones have been described earlier in the chapter. One inevitably turns to the several atlases to denominate the syndromes (Holmes et al; Jones).

2. In the group in which the abnormalities are confined to the nervous system, attention is focused on a larger number of diseases, many due to exogenous factors such as perinatal hypoxia-ischemia, pre- or postnatal infections, trauma, and so on. There are usually conspicuous neurologic signs. The degree of mental retardation is variable, depending on the location and extent of a demonstrable neuropathology. Usually the family history is negative, but careful questioning of parents regarding the pregnancy, delivery, and early postnatal period and examination of hospital records from birth may disclose the nature of the neurologic insult.

3. The third category of retardates is one in which neither somatic anomalies nor focal neurologic signs are present, or they are minimal. The more severely retarded of this special group are represented by the following disease states: autism (Asperger-Kanner syndrome), the Rett and Williams syndromes, and the fragile X and Renpenning syndromes. All of these but autism are now known to have a genetic basis, as noted earlier in the chapter, and are described together below.

The practical importance of this clinical approach is that it directs the intelligent use of laboratory procedures for confirmation of the diagnosis. CT scanning and MRI are useful in clarifying maldevelopment and neurologic diseases but are seldom helpful in the third group of cases. EEG confirms seizure discharges when there is uncertainty as to the nature of episodic neural dysfunction. Karyotyping and genetic studies are useful in group 1 and rarely in group 2 patients.

The major pitfalls to be avoided in this clinical approach is in mistaking a hereditary metabolic disease for a developmental one. Here one is helped by the fact that manifestations of the metabolic diseases are not usually present in the first days of life; they appear later and are progressive and often associated with visceral abnormalities. However, some metabolic diseases are of such slow progression that they appear almost stable, especially the late-onset ones, such as one type of metachromatic leukodystrophy, late-onset Krabbe leukodystrophy, adult adrenoleukodystrophy, and adult hexosaminidase deficiency (see Chap. 37).

**Hereditary Mental Retardations**

**Fragile X Syndrome** (See page 864) Great interest has been evinced in this syndrome, which some geneticists hold accountable, at least in part, for the preponderance of males among institutionalized retarded individuals. A large kindred in which mental retardation was inherited in an X-linked pattern was first reported by
Rett Syndrome (See page 965) This is yet another hereditary form of mental retardation, but affecting girls. None of the cases in the extensive studies of Hagberg and coworkers were male. The responsible spontaneous mutation has been shown to relate to a defect at chromosomal site Xq28, making it one of the X-linked mental retardations. A fatal outcome in boys due to a severe neonatal encephalopathy explains the expression of the disease only in girls, who are mosaicos for the mutation. The involved gene, MECP2, is responsible for suppressing various other genes at critical stages of development (see Dunn and MacLeod). It has this effect by binding to methylated DNA. Defective function of the gene leads to an alteration in synaptogenesis and neural connectivity (Neul and Zoghbi). Severe inactivation of gene expression causes classic Rett syndrome, but it has become apparent that incomplete expression and mosaicism lead to a number of partial syndromes, including nonspecific mental retardation, tremor, psychiatric disturbances, and autism-like presentations.

Prevalence studies from Sweden indicate an occurrence of 1 per 10,000 girls; thus Rett syndrome is more common than phenylketonuria. While most cases appear to be sporadic, there is a high familial incidence and some degree of concordance in twins (this is still uncertain).

The syndrome is characterized clinically by withdrawn behavior that simulates autism, dementia, ataxia, loss of purposeful hand movements, and respiratory irregularities. Highly characteristic of this syndrome is a period of 6 to 18 months of normal development followed by the rapid appearance and progression of all these signs, and then by relative stability for decades. Spasticity, muscle wasting, scoliosis, and lower limb deformities may become evident in the late stages of the illness. Hand-wringing and similar stereotypes are very typical features (and are different in subtle ways from the hand-flapping of autistic children).

Armstrong and Naidu, who have reviewed the neuropathology of Rett syndrome, have drawn attention to a number of subtle cortical abnormalities, most of which are consistent with disruption of the postnatal integrative phase of cerebral development; however, not all cases showed these abnormalities. There is generally a decrease in brain size, most marked frontally. Dendritic branching is reduced in several areas. The MRI scan is ostensibly normal, but some patients have a frontal or cerebellar atrophy in their teenage years.

Partington Syndrome This is yet another X-linked type of mental retardation, which in its fully expressed form, is associated with prominent dystonia of the hands and sometimes ataxia. Like Rett syndrome, discussed above, variations in gene expression are found to have other syndromes including myoclonic epilepsy, West syndrome, autism, and nonspecific retardation as well as lissencephaly. The mutated gene, termed Aristaless-related homeobox (ARX), is involved with regulation of protein-DNA interactions. The subject is reviewed by Sherr.

Renpenning Syndrome A similar type of hereditary, male-sex-linked mental retardation has been described by Renpenning (see page 515). The originally described family comprised 21 males in two generations of Mennonites in Western Canada whose IQs ranged from 30 to 40. As with the fragile X syndrome, female siblings may show slight degrees of retardation. Affected members were small in stature and slightly microcephalic but otherwise free of somatic and neurologic abnormalities.

Williams Syndrome This inherited form of mental retardation, which is manifest in both males and females, has also been mentioned earlier, on page 864, in relation to the chromosomal abnormalities. It is characterized by mild mental retardation but with striking retention and even precocity or superiority of musical aptitude and social amiability. In some instances a retained facility for writing permits the production of long written descriptions; yet at the same time these subjects are barely able to draw simple objects. The child is physically retarded and has minor but distinctive somatic changes (wide mouth, almond-shaped eyes, upturned nose, small pointed ears), together imparting an “elfin appearance.” The child is unusually sensitive to auditory stimuli. There is a delay in the acquisition of communicative speech and defects in visual, spatial, and motor skills, making these children seem more backward than they actually are. Striking sociability and empathy sets them apart; they represent virtually the converse of autism in this respect. Memory for musical scores—such as memorizing parts of a complete symphony after one hearing—may be prodigious. By the use of high-resolution cytogenetics, the disease has been traced in 90 percent of cases to a microdeletion on chromosome 7 in the region of the gene that controls the production of elastin (Nickerson et al). This is of interest because an index feature of these cases is a supravalvular aortic stenosis. It is not known whether there is a characteristic brain pathology, but one patient of Golden and colleagues, examined at 35 years of age, showed no cerebral abnormalities except for Alzheimer changes, mainly plaque formation in the entorinal cortex and amygdala.

Doublecortin Mutations Among the disorders of neuronal migration, lissencephaly and the related disorder of subcortical band heterotopia are usually associated with severe defects in mental development. However, in female carriers, other mutations in the doublecortin gene (DCX) on the X-chromosome have given rise to mild nondysmorphic mental retardation and cryptogenic epilepsy (see Guerrini and colleagues). Thus this disorder joins the group of X-linked mental retardations with minimal dysmorphic features.
and has implications for the understanding of X-chromosome inactivation in female carriers.

**Autism (Kanner-Asperger Syndrome; Autistic Spectrum Disorders)**

This condition was described almost simultaneously by Kanner in Baltimore (in 1943) and Asperger in Vienna (in 1944). Among the large group of retarded children, Kanner observed exceptional ones who appeared to be asocial, lacking in communicative skills both verbal and nonverbal, and committed to repetitive ritualistic behaviors. At the same time certain intellectual capacities—such as focused attention, retentive memory, skilled sensory and motor aptitudes, and capacity for visuospatial perception—were often retained or overly developed. In other words, the disorder pervaded only certain aspects of mental development. It is the gestalt of negative and positive aptitudes that sets this syndrome apart from other types of retardation. Kanner incorrectly ascribed the condition to psychosocial factors—such as a cold, aloof parent—and regarded it as a psychopathy. The implication that these children are literally “autistic”—i.e., that they have a rich inner psychic life or dream world out of relation to reality—is an assumption wholly without foundation. Asperger, whose observations included somewhat older children, less completely disabled, later ascribed the retardation (also incorrectly) to a special metabolic disease, possibly related to hyperammonemia. Opinion varied as to the relationship between the severe Kanner syndrome and the less severe Asperger syndrome. The authors have taken the position that these forms of autism represent a single syndrome of varying severity, with similar pathologic underpinnings possibly of multiple etiologies, including genetic. Some 1 percent are of normal or superior intelligence.

For reasons mentioned above, the term *autism*, drawn from psychiatry, is inappropriate but is firmly embedded in the medical lexicon. Despite many claims to the contrary, there is absolutely no evidence of a psychogenesis. (However, as Rapin points out, behavioral modification and special education are beneficial for the less severely affected.) At one time the disorder was referred to as childhood schizophrenia, but the afflicted individuals do not resemble schizophrenics, even when they reach adult years. The very early onset (preschool) of autism, the lack of delusional thinking, and different inheritance patterns are additional points against this being a type of childhood schizophrenia. Moreover, the manifestations of autism change to some extent in the course of development—a characteristic of what is called, for lack of a better label here and in Rett syndrome, a neurodevelopmental disorder.

The overall prevalence of the autistic state has been calculated at 4.5 to 20 per 10,000. Although there is said to be no familial tendency to autism, this is almost certainly incorrect; we have seen the disease in both of identical twins and in brothers, and small familial subgroups are known to exist. Autistic traits, without the full syndrome, are being found with increasing frequency in sibs and other family members, suggesting a polygenic inheritance. DeMyer found that 4 out of 11 monozygotic twins were concordant for autism and that siblings have a 50 times greater risk of developing the disorder than normal children. Bailey and also LeCouteur and associates have reported a concordance rate in monozygotic twins of 71 percent for the autistic spectrum disorder (see below) and 92 percent for an even broader phenotype of disordered social communication and stereotypic or obsessive behaviors. DeLong finds an increased incidence of manic-depressive disease in the families of one group of autistic children and superior mathematical aptitudes in other family members.

**Clinical Features** 

The autistic child is ostensibly normal at birth and may continue to be normal in achieving early behavioral sequences until 18 to 24 months of age. Then an alarming regression occurs. In some instances the abnormality appears even before the first birthday and is identified as abnormal in some way by the mother; or, if there had been a previously autistic child, she recognizes the early behavioral characteristics of the disorder. The level of activity is reduced or increased. There may be less crying and an apparent indifference to surroundings. Toys are ignored or held tenaciously. Cuddling may be resisted. Motor developments, on the other hand, proceed normally and may even be precocious. Later there may be an unusual sensitivity to all modes of sensory stimulation. Occasionally the onset appears to have a relationship to an injury or an upsetting experience.

Regardless of the time and rapidity of onset, the autistic child exhibits a disregard for other persons; this is typically quite striking but can be subtle in milder cases. Little or no eye contact is made, and the child is no more interested in another person than in an article of furniture. Preferred toys are manipulated cleverly, placed in varying lines, or rejected. Insistence on constancy of environment may reach a point where the patient becomes distressed if even a single one of his possessions has been moved from its original place and remains distressed until it is replaced. If speech develops at all, it is highly automatic (echolalic) and not used effectively to communicate. A repertoire of elaborate stereotyped movements—such as whirling of the body, manipulating an object, toe-walking, and particularly hand-flapping are characteristic. Spinning toys or running water may hold a strange fascination for the child.

It is important to point out, however, that in any sizable group of autistic children there is a wide range of deficits in sociability, drive, affect, and communicative (verbal and gestural behavior) ability, ranging from the averb, completely isolated state to one showing considerable language skill and some capacity for attachment to certain people and for scholastic achievement. In this higher-functioning group, taken to typify the Asperger syndrome, the child may be unusually adept or even supernormal in reading, calculating, drawing, or memorizing (“idiot savant”) while still having difficulty in adjusting socially and emotionally to others. Many are clumsy and inept in athletic activities. The IQ of the majority is below 70 and in 20 percent it is below 35; 1 percent, however, have normal or superior intelligence as already noted. The least degree of deficit allows success in a professional field but with handicap in the social sphere. We take the current emphasis on the term *autistic spectrum disorders* to reflect a concept that each of the core elements of autism (in social, language, cognitive, and behavioral domains) may occur in widely varying degrees of severity. This view permits a syndromic diagnosis of autism in patients with coexisting elements of other disorders, such as attention-deficit disorder and manic-depressive or obsessive-compulsive disorders and expands the diagnosis to many children who are highly functional except for gaze aversion and other “soft signs,” called “pervasive developmental disorder” (Filipek). The authors' only concern is that the clinical value of the term *autism* may prove too much about the etiology.

Rapin, drawing on a large clinical experience with autism, has carefully documented its linguistic, cognitive, and behavioral features. She uses the term *semantic-pragmatic disorder* to designate
the characteristic problem with language and behavior and to distinguis
it from other forms of developmental disorders and mental retardation. There is a striking ability to understand isolated facts but not to comprehend concepts or perceptual groupings; therefore these children and adults seem to have difficulty generalizing from an idea. Temple Grandin, a patient with a high-functioning Asper-
ger type of autism (who has written her experiences and has been described by Sacks) indicates that she thinks in pictures rather than in a semantic language. She reports a curious comfort from being tightly swaddled and has a highly developed emotional sen-
sitivity to the experiences of cattle, which has allowed her success in reforming and designing abattoirs.

Elements of autism, but not the whole syndrome with its posi-
tive and negative attributes, may appear in other diseases that interfere with brain development, specifically fragile X and Rett syn-
dromes, and fragmentary similarities are found in a few children with phenylketonuria, tuberous sclerosis, Angelman syndrome, and, rarely, Down syndrome—but these patients are easily distin-
guished from those with the far more common type of autism. Bolton and Griffiths have made the intriguing observation that au-
tistic traits in patients with tuberous sclerosis correspond to the
finding of tubers in the temporal lobe, and DeLong and Heinz point out that patients with seizures from bilateral (but not unilateral) hippocampal sclerosis may fail to develop (or may lose) language ability as well as failing to acquire social skills after a period of normal development, in a manner similar to idiopathic autism.

Etiology and Pathology of Autism The basis of childhood aut-
sism is as much a mystery today as it was when Kanner and As-
perger described it. Most of these children are physically normal except for a slightly larger head size, on average, but with no other somatic anomalies. Despite instances in which the onset of mental and behavioral regression seems to be quite sudden, no environ-
mental factors, including the often mentioned measles-mumps-
rubella (MMR) vaccination, mercury exposure, and food allergies, have been credibly connected to autism.

The EEG is normal, as is CT or MRI. The significance of cerebellar vermal changes, reported originally by Courchesne et al, remains to be determined (Filipek). In the few brains examined postmortem, no lesions of any of the conventional types have been found. In five brains studied in serial sections by Bauman and Kem-
per, smallness of neurons and increased packing density were ob-
served in the medial temporal areas (hippocampus, subiculum, entorhinal cortex), amygdala and septal nuclei, and mammillary bodies. In a subsequent review of the neuropathology, Kemper and Bauman concluded that three changes stood out: a curtailment of the normal development of neurons in the limbic system; a decrease in the number of Purkinje cells that appears to be congenital; and age-related changes in the size and number of the neurons in the diagonal band of Broca (located in the basal frontal and septal region) as well as in the cerebellar nuclei and inferior olive. The latter changes were inferred from studying the brains of autistic children who died at different ages, and they gave the appearance of a progressive or ongoing pathology that continues into adult life. These findings are in keeping with the concept of autism as a neu-
rodevelopmental disorder, but they allow only speculation regard-
ing the derivation of the clinical features of the disease. An in-
creased concentration of platelet serotonin and low serum serotonin is detected in many but not all patients; also, serum oxytocin is reduced. The biologic significance of these findings is unclear. A gene on chromosome 7q has been found by several groups and is
believed to confer a susceptibility to autism. Several other genetic loci have been implicated, suggesting that this disease reflects an interplay between polymorphisms in multiple genes, possibly influenced by environmental factors (Muhle et al).

Course, Treatment, and Prognosis The disease is essentially nonprogressive, although some patients, as they grow older, begin to manifest additional visuoperceptual or auditory defects. In the typical or classic case, the outcome is bleak, although less affected children show improvement in social relationships and schoolwork when given a serotonin reuptake inhibitor, sometimes in very small doses (DeLong; Filipek, personal communication). Administration of the peptide secretin had produced a number of anecdotal suc-
cesses, but this could not be reproduced in controlled studies (San-
dler et al).

More recently, selective serotonin reuptake inhibitors (e.g., fluoxetine, citalopram) have also shown some benefit in managing repetitive behaviors and mood swings. Medications in this class are being widely prescribed to autistic children. In addition, serious behavioral changes such as self-injurious activities, aggression, and severe tantrums have been treated with drugs such as risperidone. These almost certainly represent a therapeutic advance; but, as pointed out by Hollander and colleagues in their review of the drug treatment of autism, the patients studied were selected for the security and type of their symptoms; for this reason, these medica-
tions cannot be expected to be of help to all autistic individuals.

According to Eisenberg, who reviewed many of Kanner’s original cases and followed many other cases into adult life, one-
third never spoke and remained social isolates, one-third acquired a rudimentary language devoid of communicative value, and the remainder were functional to various degrees, possessing an af-
fected, stilted, colorless speech. It is in the latter group, representing the mildest degrees of autism, that one finds the eccentrics, the mirthless, flat personalities, unable to adapt socially and habitually avoiding eye contact but sometimes possessing certain unusual ap-
titudes in memory, mathematics, factual knowledge, history, and science. Rutter, who has written extensively on the subject, says that the degree of language impairment and lowered intelligence predicts outcome; those who do not speak by 5 years of age never learn to speak well.

Management of Mental Retardation

Since there is little or no possibility of treating most of the diseases underlying mental retardation and there is no way of restoring func-
tion to a nervous system that is developmentally subnormal, the objective is to assist in planning for the patient’s care, training, education, and social adjustment. The parents must be guided in forming realistic attitudes and expectations. Psychiatric and social counseling may help the family to maintain gentle but firm support of the patient so that he or she can acquire, to the fullest extent possible, good work habits and a congenial personality.

Most individuals with an IQ above 60 and no other handicaps can be trained to live an independent life: special schooling may enable them to learn skills useful in a vocation. Social factors that contribute to underachievement must be sought and eliminated if possible.

If the IQ is below 20, institutionalization is almost inevitable, for few families can provide the long-term custodial care that is needed. Well-run institutions are usually better than community homes because they offer many more facilities (medical, educa-
tional, recreational). Often institutional care is necessary for individuals with IQs of 20 to 50. Patients in this group, if stable in temperament and relatively well adjusted to society, can work under supervision, but they rarely become vocationally independent. For the more severely retarded, special training in hygiene and self-care is the most that can be expected.

Great care must be exercised in recommending institutionalization. Whereas the need will be all too apparent in the gravely handicapped, the more mildly handicapped may be more difficult to evaluate at an early age. As stated earlier, psychologic tests alone are not altogether trustworthy. It is best to observe the patient over a period of time. As noted in Chap. 28, the method of evaluation suggested long ago by Fernald has a ring of soundness, albeit in quite dated terms. It should include observations of (1) the physical, medical, and neurologic findings; (2) family background; (3) developmental history; (4) school progress or lack thereof; (5) performance tests; (6) social behavior; (7) industrial efficiency; (8) behavioral disinhibition, which was called in Fernald’s time “moral behavior”; and (9) intelligence as measured by psychological tests.

CHAPTER 38  DEVELOPMENTAL DISEASES OF THE NERVOUS SYSTEM  893

CHAPTER 39

DEGENERATIVE DISEASES OF
THE NERVOUS SYSTEM

The adjective *degenerative* has no great appeal to the modern neurologist. For one thing, it has an unpleasant nonmedical connotation, referring as it does to a state of moral turpitude or deviant behavior. More important, it is not a satisfactory term medically, since it implies an inexplicable decline from a previous level of normalcy to a lower level of function—an ambiguous conceptualization of disease that satisfies neither theoretician nor scientist.

It is becoming increasingly evident that many of the diseases included in this category depend on genetic factors, or at least they appear in more than one member of the same family, in which case they are more properly designated as *heredodegenerative*. Even more diseases, not differing in any fundamental way from the heredodegenerative ones, occur sporadically, i.e., as isolated instances in given families. For diseases of this type, Gowers in 1902 suggested the term *abiotrophy*, by which he meant a lack of “vital endurance” of the affected neurons, resulting in their premature death. This concept embodies an untested, unproven hypothesis—that aging and degenerative changes of cells are based on the same process. Understandably, contemporary neuropathologists are reluctant to attribute to simple aging the diverse processes of cellular death. This concept embodies an untested, unproven hypothesis—understandable conceptually, is an ambiguous conceptus.

The reader may be perplexed by the inconsistent use of the terms *atrophy* and *degeneration*, both of which are applied to diseases of this category. Spatz argued that on purely histopathologic grounds they are different. *Atrophy* specifies a gradual wasting and loss of a system of neurons, leaving in their wake no degradative products and only a sparsely cellular, fibrous gliosis. *Degeneration* refers to a more rapid process of neuronal, myelin, or tissue breakdown, the degradative products of which evoke a more vigorous reaction of phagocytosis and cellular astrogliosis. The difference lies in both the speed and the type of breakdown. It is of some interest that many of the diseases characterized by degeneration, in Spatz’s sense of the term, are now known to be of metabolic origin, while very few of the purely atrophic ones have been shown to have a metabolic basis.

There are also, within recent memory, several examples of diseases that were formerly classed as degenerative but are now known to have a metabolic, toxic, or nutritional basis or to be caused by a “slow virus” or a nonviral transmissible agent. It seems reasonable to expect that with increasing knowledge, more and more diseases whose causes are now unknown will find their way into these categories.

As was pointed out in Chap. 29, on aging, more than half of the normal life cycle of the organism involves a slow deterioration of organ function. Such changes in the nervous system are manifest in every sensory and motor system and in all cerebral functions. The basis of these aging changes is theoretically at the neuronal level, but it is not fully understood. A fundamental problem is the distinction of these aging deteriorations from degenerative disease. When the latter appears in adult life, one must assume that the clinical presentation is modified to some extent by life-cycle phenomena—the patient’s function being a gestalt of both processes.

Their separation is of fundamental importance in diagnosis and therapeutics.

In recent times much new and essential information has been gained regarding the biologic derangements that lead to neuronal death and dysfunction by investigating the inherited forms of degenerative diseases. The application of the techniques of molecular genetics to the field of neurodegenerative disease have given stunning results. Even when the hereditary forms of a degenerative condition are rare in comparison to sporadic types and do not entirely conform on clinical grounds to idiopathic disease, general principles of cellular biology have exposed mechanisms common to both familial and sporadic forms of the same disorder. This approach holds great promise for effective treatment of what herebefore have been considered progressive and incurable diseases. For these reasons, and because the well educated neurologist should have some understanding of this evolving field, there is in this chapter more emphasis on mutations that cause degenerative neurologic conditions than had been given in previous editions of the book.

In view of this emphasis, it has been proposed that all degenerative diseases be classified according to their genetic and molecular abnormalities. However, when one notes the diversity of pathologic change that may accompany a single, seemingly unitary gene abnormality or, reciprocally, the diversity of genetic defects that may underlie a single phenotype, this type of classification, while informative, does not prove immediately helpful to the clinician. In other words, the practice of creating new disease categories to encompass all of the molecular and pathologic changes associated with a particular type of neuronal degeneration offers no great advantage in practice. After all, the patient does not complain of a particular cellular pathology. We believe the only valid approach for the clinician is through an awareness of constellations of clinical features. Restated, until such time as the causation of the degenerative neurologic diseases is known, there must be a name and a place for a group of diseases that have no known cause and are united only by the common attribute of gradually progressive disintegration of part or parts of the nervous system. In deference to traditional practice, these diseases are collected here under the rubric *degenerative diseases*. Nonetheless, as already mentioned, the knowledgeable clinician should be aware of those diseases that are attributable entirely to a gene mutation as well as the ongoing endeavors to understand the cellular mechanisms being exposed as a result of the study of genetic forms of neurologic disease.

General Clinical Characteristics of
Degenerative Diseases

The diseases included in the degenerative category have two outstanding characteristics: (1) they tend to affect specific parts or functional systems of the nervous system and (2) they begin insidiously, after a long period of normal nervous system function, and pursue a gradually progressive course that continues for many
years, often a decade or longer. In respect to their temporal evolution, these diseases differ from most of the metabolic and slow viral disorders. Frequently it is impossible to assign a date of onset. Sometimes, the patient or the patient’s family gives a history of abrupt appearance of disability, particularly if some injury, infection, surgical procedure, or other memorable event coincided with the initial symptoms. Often a skillfully taken history will reveal that the patient or family had been aware of a pre-existent condition, the subtle symptoms of which had been present for some time but had attracted little attention. Whether trauma or other stress can actually evoke or aggravate a degenerative disease is a question that cannot be answered with absolute certainty. Anyone who states otherwise must offer evidence that at present is purely anecdotal. Instead, these degenerative disease processes by their very nature appear to develop de novo, without relation to known antecedent events, and their symptomatic expressions are late events in the pathologic process, occurring only when the degree of neuronal loss reaches or exceeds the “safety factor” for the functioning of a particular neuronal system. Irreversibility of clinical manifestations is another feature common to all the neurodegenerative conditions.

The familial occurrence of disease is of great importance both clinically and for scientific reasons, as just mentioned, but it must be emphasized again that such information is often difficult to obtain on first contact with the patient. The family may be small or widely scattered, so that the patient is unaware of the health of other members. The patient or the patient’s relatives may be ashamed to admit that a neurologic disease has “tainted” the family. Furthermore, it may not be realized that an illness is hereditary if other members of the family have a much more or much less severe form of the disorder than the patient. Sometimes, in the latter case, only the careful examination of other family members will disclose the presence of a hereditary disease. Also, it should be remembered that familial occurrence of a disease does not necessarily mean that it is inherited but may indicate instead that more than one member of a family had been exposed to the same infectious or toxic agent.

As a rule, the degenerative diseases of the nervous system run a ceaselessly progressive course and with few exceptions are uninfluenced by any medical or surgical measures, so that dealing with a patient with this type of illness may be an anguishing experience for all concerned. However, some of these diseases are characterized by periods of relative stability; moreover, many symptoms (e.g., those of Parkinson disease) can be alleviated by medication. The process of pathologic neuronal degeneration is quite different in that it refers to a series of changes in mature neurons that occur over a protracted period of time, leading to cell death and often leaving a discrete glial scar. In many models, this process can involve activation of programmed cell death genes, although the time course and cellular morphology are not apoptotic in the original sense of the term. Probably, mechanisms other than programmed cell death will prove central to understanding the degenerative diseases, and it is becoming apparent that the clinical features of these conditions are manifest even before cellular destruction occurs. For example, interference with synaptic signaling and dysfunction of supporting glial cells are equally important features.

Finally, it will become apparent in the following discussion that a common theme in the modern study of degenerative diseases is that of aggregation of normal cellular proteins such as amyloid, synuclein, ubiquitin, and huntingtin. In some cases, the protein is overproduced as a result of the simple fact of a triplication or overactivity of its gene. In other instances, enzymatic cleavage of a normal precursor protein yields a product with physical properties...
that lead to aggregation (as happens with amyloid in Alzheimer disease) or, in others, there may be failure of the normal mechanisms of protein removal, resulting in the accumulation of a normal cellular protein. The biologic and the physicochemical properties of these proteins have therefore assumed great importance. The mechanisms by which these various proteins interfere with cellular function and ultimately cause cell death is an area of modern research.

**CLINICAL CLASSIFICATION**

Since grouping of the degenerative diseases in terms of etiology is not currently possible (except that in some hereditary or genetic factor can be recognized), we resort, for practical purposes, to a division based on the presenting clinical syndromes and their pathologic anatomy. Although this is the most elementary mode of classification of naturally occurring phenomena, it is a necessary prelude to diagnosis and scientific study and preferable to a hap-hazard listing of diseases by the names of the neurologists or neuropathologists who first described them. For reasons given in the introduction to this chapter, this approach is also preferable to genetic classifications in analyzing the problem presented by an individual patient.

I. Syndrome of progressive dementia, other neurologic signs being absent or inconspicuous
   A. Diffuse cerebral atrophy
      1. Alzheimer disease
      2. Diffuse cerebral cortical atrophy of non-Alzheimer type
      3. Some cases of Lewy body dementia
   B. Circumscribed cerebral atrophies
      1. Pick disease (lobar sclerosis)
      2. Frontotemporal dementia

II. Syndrome of progressive dementia in combination with other neurologic abnormalities
   A. Huntington chorea
   B. Lewy body disease
   C. Some cases of Parkinson disease
   D. Corticobasal ganglionic degeneration
   E. Cortical-striatal-spinal degeneration (Jakob) and the dementia—Parkinson—amyotrophic lateral sclerosis complex (Guamanian and others)
   F. Cerebrocerebellar degeneration
   G. Familial dementia with spastic paraparesis, amyotrophy, or myoclonus
   H. Polyglucosan body disease
   I. Frontotemporal dementia with parkinsonism or ALS
   J. Primary progressive aphasia

III. Syndrome of disordered posture and movement
   A. Parkinson disease
   B. Striatonigral degeneration with or without autonomic failure (Shy-Drager syndrome) and olivopontocerebellar atrophy (multiple system atrophy)
   C. Progressive supranuclear palsy
   D. Dystonia musculorum deformans (torsion spasm)
   E. Hallervorden-Spatz disease
   F. Huntington chorea
   G. Other inherited chéreas
   H. Corticobasal ganglionic degeneration
   I. Lewy body disease

J. Dentatorubropallidoluysian degeneration (DRPLA)
K. Restricted dystonias, including spasmotic torticollis and Meige syndrome
L. Familial tremors, essential tremor
M. Multiple tic disease (Gilles de la Tourette syndrome)
N. Acanthocytic chorea

IV. Syndrome of progressive ataxia
   A. Spinocecrebellar ataxias (early onset)
      1. Friedreich ataxia
      2. Non-Friedreich, early-onset ataxia (with retained reflexes, hypogonadism, myoclonus, and other disorders)
   B. Cerebellar cortical ataxies
      1. Holmes type of familial pure cerebellar-olivary atrophy
      2. Late-onset cerebellar atrophy of Marie, Foix, and Alajouanine
   C. Complicated cerebellar ataxias (later-onset ataxia with brainstem and other neurologic disorders)
      1. Olivopontocerebellar degenerations (OPCA)
         a. Clinically pure (Déjerine-Thomas type)
         b. With extrapyramidal and autonomic degeneration (multiple system atrophy)
         c. Conjoined with spinocerebellar degeneration (Menzel type)
      2. Dentatorubral degeneration (Ramsay Hunt type)
      3. Dentatorubropallidoluysian atrophy (DRPLA)
      4. Machado-Joseph-Azorean disease
      5. Other complicated late-onset, autosomal dominant ataxias (including Harding’s types 1, 2, and 3) with pigmentary retinopathy, ophthalmoplegia, slow eye movements, polyneuropathy, optic atrophy, deafness, extrapyramidal features, and dementia

V. Syndrome of slowly developing muscular weakness and atrophy
   A. Motor disorders with amyotrophy: motor system disease
      1. Amyotrophic lateral sclerosis
      2. Progressive spinal muscular atrophy
      3. Progressive bulbar palsy
      4. Hereditary forms of progressive muscular atrophy and spastic paraplegia
      5. Motor neuron disease with frontotemporal dementia
   B. Spastic paraplegia without amyotrophy
      1. Primary lateral sclerosis
      2. Hereditary spastic paraplegia (Strümpell-Lorrain)

VI. Sensory and sensorimotor disorders (neuropathies) (See Chap. 46)
   A. Hereditary sensorimotor neuropathies—peroneal muscular atrophy (Charcot-Marie-Tooth); hypertrophic interstitial polyneuropathy (Déjerine-Sottas); and others

VII. Syndrome of progressive blindness or ophthalmoplegia with or without other neurologic disorders
   A. Pigmentary degeneration of retina (retinitis pigmentosa)
   B. Stargardt disease
   C. Mitochondrial disorders sometimes classified as degenerative
1. Progressive external ophthalmoplegia with or without deafness or other system atrophies (Kearns-Sayre syndrome)
2. Leber hereditary optic neuropathy

VIII. Syndromes characterized by neurosensory deafness (See Chap. 15)
A. Pure neurosensory deafness
B. Hereditary hearing loss with retinal diseases
C. Hereditary hearing loss with system atrophies of the nervous system

DISEASES CHARACTERIZED MAINLY BY PROGRESSIVE DEMENTIA

Alzheimer Disease

This is the most common and important degenerative disease of the brain, having to an increasing degree an immense societal impact. Some aspects of the intellectual deterioration that characterizes this disease have already been described in Chap. 21, under “The Neurology of Dementia,” and the relationship of this disease to the aging process has been fully discussed in Chap. 29. There it was pointed out that some degree of shrinkage in size and weight of the brain, i.e., “atrophy,” is an inevitable accompaniment of advancing age, but that these changes alone are of relatively slight clinical significance and uncertain structural basis (e.g., whether the loss of brain weight is due to a simple depletion of neurons). By contrast, severe degrees of diffuse cerebral atrophy that evolve over a few years are invariably associated with dementia, and the underlying pathologic changes in these cases most often prove to be those of Alzheimer disease. As also commented in Chap. 29, the rate of cerebral atrophy, specifically of the hippocampus and medial parts of the temporal lobes, is accelerated in the early stages of Alzheimer disease, and longitudinal studies by magnetic resonance imaging (MRI) can identify individuals who will subsequently develop the disease (Rusinick). These observations have significance in relation to future treatment of Alzheimer disease at a stage of potential reversibility.

The now outdated practice of giving Alzheimer disease and senile dementia the status of separate diseases was attributable to the relatively young age (51 years) of the patient originally studied by Alois Alzheimer in 1907. Such a division is illogical, since the two conditions, except for their age of onset, are clinically and pathologically indistinguishable. There is, in fact, a smooth, exponential, age-dependent increase in incidence after 40 years of age. Whether it is useful to classify separately the differing here-

dofamilial forms of Alzheimer disease is an open question, but these occur infrequently enough that they need not be differentiated from the native disease for the purposes of clinical work.

Epidemiology Although Alzheimer disease has been described at every period of adult life, the majority of patients are in their sixties or older; a relatively small number have been in their late fifties or younger. It is one of the most frequent mental illnesses, making up some 20 percent of all patients in psychiatric hospitals and a far larger proportion in nursing homes. In the United States, in 17 series comprising 15,000 persons over the age of 60 years, the mean incidence of moderate to severe dementia was calculated to be 4.8 percent (Wang). In Rochester, Minnesota, the incidence rate for dementia in general is 187 cases per 100,000 population per year, and for Alzheimer disease, 123 cases per 100,000 annually (Schoenberg et al).

These staggering statistics may be viewed from another perspective. The incidence rate of clinically diagnosed Alzheimer disease is similar throughout the world, and it increases comparably with age, approximating 3 new cases yearly per 100,000 persons below age 60 and 125 new cases per 100,000 of those over 60. The prevalence of the disease per 100,000 population is near 300 in the group aged 60 to 69; it is 3200 in the 70-to-79 group and 10,800 in those over age 80. In the year 2000, there were an estimated 2 million persons with Alzheimer disease in the United States. Prevalence rates, which depend also on overall mortality, are three times higher in women, although it does appear that the incidence of new cases is only slightly disproportionate in women. The survival of patients with Alzheimer disease is reduced to half the expected rate, mainly because of respiratory and cardiovascular causes and inanition but also for other reasons that are not entirely clear.

Several putative epidemiologic risk factors for Alzheimer disease—such as birth order, mother’s age at birth, family history of Down syndrome, or head injury—seem marginal at best and in some instances may be due to selection bias. Whether low educational attainment is a risk factor for the development of Alzheimer disease or, conversely, whether cognitively demanding occupations protect against dementia has not been settled, but some provocative data indicating that this may be so have been presented in Chap. 21 (Katzman; Cobb et al).

The familial occurrence of Alzheimer disease has been well established. In fewer than 1 percent of such cases there is a domin-

inant inheritance pattern (Nee et al; Goudsmit et al; see further on, in the section on pathogenesis). Reports of substantial familial aggregations of dementia without a specific pattern of inheritance also suggest the operation of more than one genetic factor. Several studies have documented a significant increase in the risk of ostensibly sporadic Alzheimer disease among first-degree relatives of patients with this disorder. Again, this risk is disproportionately greater in females, adding to the evidence that women in general are at slightly higher risk for Alzheimer disease (Silverman et al). Li and coworkers have provided evidence that patients with an earlier age of onset of Alzheimer disease (before age 70) are more likely to have relatives with the disease than are patients with later onset. Genetic studies are difficult because the disease does not appear at the same age in a given proband. Even in identical twins, it may develop at the age of 60 years in one of the pair and at 80 years in the other. Death from other diseases may prevent its detection.

Clinical Features (See also Chap. 21) The onset of mental changes is usually so insidious that neither the family nor the patient can date the time of its beginning. Occasionally, however, it is brought to attention by an unusual degree of confusion in relation to a febrile illness, an operation, mild head injury, or the taking of medication. Other patients may present with complaints of dizziness, mental foginess, nondescript headaches, or other vaguely expressed and changeable somatic symptoms.

The gradual development of forgetfulness is the major symp-
tom. Small day-to-day happenings are not remembered. Seldom-used names are particularly elusive. Little-used words from an earlier period of life also tend to be lost. Appointments are forgotten and possessions misplaced. Questions are repeated again and again, the patient having forgotten what was just discussed. It is said that remote memories are preserved and recent ones lost (Ribot’s law of memory), but this is only relatively true; it is difficult to check
the accuracy of ancient memories. Albert and associates, who tested the patient’s recognition of dated political events and pictures of prominent people past and present, found that some degree of memory loss extends to all decades of life (neuropsychologic testing is discussed further on).

Once the memory disorder has become pronounced, other failures in cerebral function become increasingly apparent. The patient’s speech is halting because of failure to recall the needed word. The same difficulty interrupts writing. Vocabulary becomes restricted and expressive language stereotyped and inflexible. Comprehension of spoken words seems at first to be preserved, until it is observed that the patient does not carry out a complicated request; even then it is uncertain whether the request was not understood because of inattention or was forgotten. Almost imperceptible at first, these disturbances of language become more apparent as the disease progresses. The range of vocabulary and the accuracy of spelling are reduced. Finally, after many years of illness, there is a failure to speak in full sentences; the finding of words requires a continuous search; and little that is said or written is fully comprehended. There is a tendency to repeat a question before answering it, and later there may be a rather dramatic repetition of every spoken phrase (echolalia). The deterioration of verbal skills has by then progressed beyond a groping for names and common nouns to an obvious anomie aphasia. Other elements of receptive and executive aphasia are later added, but discrete aphasias of the Broca or Wernicke type are characteristically lacking. In general there is a paucity of speech and a quantitative reduction in mentation.

Skill in arithmetic suffers a similar deterioration. Faults in balancing the checkbook, mistakes in figuring the price of items and in making the correct change—all these and others progress to a point where the patient can no longer carry out the simplest calculations (acalculia or dyscalculia).

In some patients, visuospatial orientation becomes defective. The car cannot be parked; the arms do not find the correct sleeves of the jacket or shirt; the corners of the tablecloth cannot be oriented with the corners of the table; the patient turns in the wrong direction on the way home or becomes lost. The route from one place to another cannot be described, nor can given directions be understood. As this state worsens, the simplest of geometric forms and patterns cannot be copied.

Late in the course of the illness, the patient forgets how to use common objects and tools while retaining the necessary motor power and coordination for these activities. The razor is no longer correctly applied to the face; the latch of the door cannot be unfastened; and eating utensils are used awkwardly. Finally, only the most habitual and virtually automatic actions are preserved. Tests of commanded and demonstrated actions cannot be executed or imitated. Ideational and ideomotor apraxia are the terms applied to the advanced forms of this motor incapacity (pages 48 and 402).

As these many amnesic, aphasis, agnosic, and apraxic deficits declare themselves, the patient at first seems unchanged in overall motility, behavior, temperament, and conduct. Social graces, whatever they were, are retained in the initial phase of the illness, but troublesome alterations gradually appear in this sphere as well. Unprofitable business deals may be made. Restlessness and agitation or their opposites—inertia and placidity—become evident. Dressing, shaving, and bathing are neglected. Anxieties and phobias, particularly fear of being left alone, may emerge. A disturbance of the normal day and night sleep patterns is prominent in some patients. A poorly organized paranoid delusional state, sometimes with hallucinations, may become manifest. The patient may suspect his elderly wife of having an illicit relationship or his children of stealing his possessions. A stable marriage may be disrupted by the patient’s infatuation with a younger person or by sexual indiscretions, which may astonish the community. The patient’s affect coarsens; he is more egocentric and indifferent to the feelings and reactions of others. A gluttonous appetite sometimes develops, but more often eating is neglected, with gradual weight loss. Later, grasping and sucking reflexes and other signs of frontal lobe disorder are readily elicited (Neary et al), sphincteric continence fails, and the patient sinks into a state of relative akinesia and mutism, as described in Chap. 21.

Difficulty in locomotion, a kind of unsteadiness with shortened steps but with only slight motor weakness and rigidity, frequently supervenes. Elements of parkinsonian akinesia and rigidity and a fine tremor can be perceived in patients with advanced motor disability. Ultimately the patient loses the ability to stand and walk, being forced to lie inert in bed and having to be fed and bathed, and the legs may curl into a fixed posture of paraplegia in flexion (persistent vegetative state; page 304).

The symptomatic course of this tragic illness usually extends over a period of 5 or more years, but judging from studies of Down cases, the pathologic course has a much longer asymptomatic duration. This concept is supported by the detailed studies of Linn and colleagues, who found that a lengthy “preclinical” period (7 years or more) of stepwise decline in memory and attention span preceded the clinical diagnosis. Surprisingly, throughout this period, corticospinal and corticosenso functions, visual acuity, ocular movements, and visual fields remain relatively intact. If there is hemiplegia, homonymous hemianopia, etc., either the diagnosis of Alzheimer disease is incorrect or the disease has been complicated by a stroke, tumor, or subdural hematoma. Exceptions to this statement are rare. The tendon reflexes are little altered and the plantar reflexes almost always remain flexor. There is no true sensory or cerebellar ataxia. Convulsions are rare until late in the illness, when up to 5 percent of patients reportedly have infrequent seizures. Occasionally, widespread myoclonic jerks or mild choreoathetotic movements are observed late in the illness. Grand mal seizures occur in a small number of patients during the end stages of the disease. Eventually, with the patient in a bedfast state, an intercurrent infection such as aspiration pneumonia or some other disease mercifully terminates life.

The sequence of neurologic disabilities may not follow this described order, and one or another deficit may take precedence, presumably because the disease process, after becoming manifest in the memory cortex of the temporal lobes, may affect one particular part of the associative cortex earlier or more severely in one patient than in another. This allows a relatively restricted deficit to become the source of early medical complaint long before the full syndrome of dementia has declared itself. We have observed four limited deficits of this type, as follows:

1. **Korsakoff amnesic state.** The early stages of Alzheimer disease are usually dominated by a disproportionate failure of retentive memory, with integrity of other cognitive abilities. This may be the sole difficulty for years. In such patients, immediate memory (essentially a measure of attention), tested by the capacity to repeat a series of numbers or words, is essentially intact; it is the short- and long-term (retentive) memory that fails. Retentive memory may become impaired
to the point where the patient can recall nothing of what she had learned a minute or two previously. Yet as a business executive, for example, he may continue to make acceptable decisions if the work utilizes long-established habit patterns and practices. In such cases, the temporal horns tend to be enlarged more than the rest of the ventricular system, reflecting the disproportionate atrophy of the inferomedial temporal lobes.

2. **Dysnomia.** The forgetting of words, especially proper names, may first bring the patient to a neurologist. Later the difficulty involves common nouns and progresses to the point where fluency of speech is seriously impaired. Every sentence is broken by a pause and search for the wanted word; if this is not found, a circumlocution is substituted or the sentence is left unfinished. When the patient is given a choice of words, including the one that was missed, there may be a failure of recognition. Repetition of the spoken words of others, at first flawless, later brings out a lesser degree of the same difficulty. A useful test for the failure to find names (dysnomia), which is probably the most common abnormality of language in this disease, is the category-fluency test. The naming defect is evident with even simple tests, e.g., asking the patient to generate a list of farm animals or car brands—a test that may elicit only three or four responses. A more extensive examination entails asking the patient to name as many items as possible in each of three categories in 1 min—vegetables, tools, and clothing. Alzheimer patients fall below a score of 50 items. Other components of language may be relatively intact, but before long it is evident that the patient does not understand all that he hears or reads. In contrast, nonverbal memory and the ability to calculate and make simple judgments may still be preserved. Duplicating our own experience, Mesulam and Chawluk and their colleagues have described patients in whom an aphasic disorder began with anomia and eventually affected reading, writing, and comprehension without the additional intellectual and behavioral disturbances of dementia. In our own observation, such patients, if followed for a sufficiently long period, develop a more general dementia, sometimes as long as 5 years or more after the onset of aphasia. This syndrome of “primary progressive aphasia” also represents a focal degenerative disorder (lobar atrophy of Pick or frontotemporal dementia), distinct from Alzheimer disease (Lippa et al, Kirshner et al). Usually the electroencephalogram (EEG) is normal or shows only a mild degree of left frontotemporal slowing, but MRI may disclose a focal atrophy of the language areas (Caselli et al).

3. **Visual-spatial disorientation.** Parieto-occipital functions are sometimes deranged in the course of Alzheimer disease and may fail while other functions are relatively preserved. This has been termed “posterior cortical dementia” (see Renner et al). As remarked above and in Chap. 22, prosopagnosia (impaired facial recognition), losing one’s way in familiar surroundings or inability to interpret a road map, to distinguish right from left, or to park or garage a car, and difficulty in setting the table or dressing are all manifestations of a special failure to orient the schema of one’s body with that of surrounding space. Exceptionally there is a neglect of stimuli in one visual field. Some of these patients develop the Balint syndrome or Gerstmann syndrome (Tang-Wai et al).

4. **Paranoia and other personality changes.** Frequently, at some point in the development of senile dementia, the most prominent event is the occurrence of paranoia or bizarre behavior. This may appear before the more obvious memory or language defects announce themselves. The patient becomes convinced that relatives are stealing his possessions or that an elderly and even infirm spouse is guilty of infidelity. He may hide his belongings, even relatively worthless ones, and go about spying on family members. Hostilities arise, and wills may be altered irrationally. Many of these patients are constantly worried, tense, and agitated. Of course, paranoid delusions may be part of a depressive psychosis and of other dementias, but most of the senile patients in whom paranoia is the presenting problem seem not to be depressed, and their cognitive functions are for a time relatively well preserved. It is tempting to think that a very early degenerative change of the limbic cortices has exposed a lifelong trait of suspiciousness, but this is purely hypothetical. Sometimes other oddities of behavior will announce the oncoming dementia. Social indiscretions, rejection of an old friend, embarking on an imprudent financial venture, or an amorous pursuit that is out of character are examples of these types of behavioral change.

Some clinicians attempt to subdivide the Alzheimer dementia syndrome into subtypes. Amnestic defect without lexical-semantic abnormalities represents more than 50 percent of cases. Chin and coworkers observed more prevalent and severe language disorder and more rapid progression in early-onset familial cases. Others point to a disproportionately severe defect in praxic functions and a greater tendency to abnormal EEG findings in such cases. Whether such distinctions represent fundamental differences in the disease process is questionable.

It has been our impression that each of the restricted clinical disorders described above is only relatively pure. Careful testing of mental function—and this is of diagnostic importance—frequently discloses subtle abnormalities in several cognitive spheres. Initially, most patients have a disproportionate disorder of the temporoparietal cortices, reflected by an earlier impairment on the performance parts of the Wechsler Adult Intelligence Scale. Within several months to a year or two, the more generalized aspects of mental deterioration become apparent, and the aphasic-agnosic-apraxic aspects of the syndrome become increasingly prominent. If one of the foregoing restricted deficits remains uncomplicated over a period of years, one is justified in suspecting some cause other than Alzheimer disease, such asBinswanger disease, hydrocephalus, frontotemporal dementia (see further on), or embolic infarction of one part of the temporal or parietal lobe. Also, as stated earlier, a hemianopic visual field defect, cortical sensory loss, or hemiparesis is seldom if ever due to Alzheimer disease. However, more complex disturbances of visual perception—taking the form of impaired recognition of objects (object agnosia) or faces (prosopagnosia), visual scanning, color identification, stereocuity, separation of figures from background, and hand-eye coordination—are frequent in the more advanced stages (Mendez et al). Rarely there is a partial or even a complete Balint syndrome.

While it is true that most patients with Alzheimer disease walk normally until relatively late in their illness, infrequently a short-stepped gait and imbalance draw attention to the disease and worsen slowly for several years before cognitive manifestations become evident. The general decrepitude in appearance that accom-
companies the middle and late stages of the disease in many patients was commented on in Chap. 21.

For research purposes and to establish certain inclusive and exclusive criteria for the diagnosis of Alzheimer disease, a work group of the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) and the Alzheimer’s Disease and Related Diseases Association (ADRDA) have proposed the following diagnostic criteria: (1) dementia defined by clinical examination, the Mini-Mental Scale (page 382), the Blessed Dementia Scale, or similar mental status examination; (2) age of patient (over 40 years); (3) deficits in two or more areas of cognition and progressive worsening of memory and other cognitive functions—such as language, perception, and motor skills (praxis); (4) absence of disturbed consciousness; and (5) exclusion of other brain diseases (McKhann et al; Tierney et al). Using these criteria, the correct diagnosis is achieved in more than 85 percent of patients. Most cases are identifiable without resorting to restrictive criteria such as these, especially if the patient is observed serially over a period of months or years.

Pathology In the advanced stages of the disease, the brain presents a diffusely atrophied appearance and its weight is usually reduced by 20 percent or more. Cerebral convolutions are narrowed and sulci are widened. The third and lateral ventricles are symmetrically enlarged to a varying degree. Usually the atrophic process involves the frontal, temporal, and parietal lobes, but cases vary considerably. The extreme atrophy of the hippocampus—the most prominent finding, visible on MRI (mainly coronal images)—is diagnostic in the proper clinical circumstances. Microscopically, there is widespread loss of nerve cells. Early in the disease this is most pronounced in layer II of the entorhinal cortex. In addition to pronounced neuronal loss in the hippocampus, adjacent parts of the medial temporal cortex—namely, the parahippocampal gyrus and subiculum—are affected. The anterior nuclei of the thalamus, septal nuclei, and diagonal band of Broca, amygdala, and particular brainstem parts of the monoaminergic systems are also depleted. The cholinergic neurons of the nucleus basalis of Meynert (the substantia innominata) and locus ceruleus are also reduced in number, a finding that at one time aroused great interest because of its putative role in memory loss (see below). In the cerebral cortex, the cell loss predominantly affects the large pyramidal neurons. Residual neurons are observed to have lost volume and ribonucleoprotein; their dendrites are diminished and crowd upon one another owing to the loss of synapses and neuropil. Astrocytic proliferation follows as a compensatory or reparative process, most prominent in layers III and V.

In addition, three microscopic changes give this disease its distinctive character (Fig. 39-1): (1) The presence within the nerve cell cytoplasm of thick, fiber-like strands of silver-staining material, often in the form of loops, coils, or tangled masses (Alzheimer neurofibrillary changes or “tangles”). These strands are composed of a hyperphosphorylated form of the microtubular protein “tau” and appear as pairs of helical filaments when studied ultrastructurally. (2) Spherical deposits of amorphous material scattered throughout the cerebral cortex and most easily seen with periodic acid–Schiff (PAS) and silver-staining methods; the core of the aggregates is the protein amyloid, surrounded by degenerating nerve terminals (senile or neuritic plaques). Amyloid is also scattered throughout the cerebral cortex in a nascent “diffuse” form, without organization or core formation and appreciated mainly by immunohistochemical methods, as well as in the walls of small blood vessels near the plaques—so-called congophilic angiopathy. (3) Granulovacuolar degeneration of neurons, most evident in the pyramidal layer of the hippocampus.

Neuritic plaques and neurofibrillary changes are found in all the association areas of the cerebral cortex, but it is the neurofibrillary tangles and neuronal alterations and loss, not the plaques, that correlate best with the severity of the dementia (Arriagada et al). If any part of the brain is disproportionately affected, it is the hippocampus, particularly the CA1 and CA2 zones (of Lorente de Nó) and the entorhinal cortex, subiculum, and amygdala. These parts have abundant connections with other parts of the temporal lobe cortex and dentate gyrus of the hippocampus and undoubtedly account for the amnesic component of the dementia. The parietal lobes are another favored site. Only a few tangles and plaques are found in the hypothalamus, thalamus, periaqueductal region, pontine tegmentum, and granule-cell layer of the cerebellum.

Experienced neuropathologists recognize a form of Alzheimer disease, particularly in older patients (75 years), in which there are senile plaques but few or no neuronal tangles (over 20 percent of 150 cases reported by Joachim et al). Another problem for the neuropathologist is to distinguish between the normal aged brain and that of Alzheimer disease. It is not unusual to find a scattering of senile plaques in individuals who were thought to be mentally normal during life. Henderson and Hubbard studied 27 demented individuals aged 64 to 92 years and 20 age-matched, nondemented controls. In the former, 3 to 38 percent of the hippocampal neurons contained neurofibrillary tangles; in all but 2 of the controls, the number of hippocampal neurons with tangles fell below 2.5 percent. Hence, the difference between plaques and tangles in the aging brain and in Alzheimer disease is largely quantitative.

Also of interest is the observation of Joachim and associates that 18 percent of Alzheimer cases had sufficient neuronal loss and Lewy bodies in the substantia nigra to justify a diagnosis on histopathologic grounds of Parkinson disease. Leverenz and Sumi found that 25 percent of their Alzheimer patients showed the pathologic (and clinical) changes of Parkinson disease—a much higher incidence than can be attributed to chance. Similarly, of 11 patients with progressive supranuclear palsy (discussed further on) reported by Gearing and coworkers, 10 were demented and 5 had the neuropathologic features of Alzheimer disease. These mixed cases, including those patients with Pick disease, present problems...
not only of classification but also in understanding the neurobiology of these degenerative diseases. This subject is discussed further on in the section on Parkinson disease.

It is of historical interest that Alzheimer was not the first to describe plaques, one of the hallmarks of this pathologic state. These miliary lesions (“Herdenchen”) had been observed in senile brains by Blocq and Marinosco in 1892 and were named senile plaques by Simchowicz in 1910. In 1907, Alzheimer described the case of a 51-year-old woman who died after a 5-year illness characterized by progressive dementia. Throughout the cerebral cortex he found the characteristic plaques, but he also noted—thanks to the use of Bielschowsky’s newly devised silver impregnation method—a clumping and distortion of fibrils in the neuronal cytoplasm, the neurofibrillary change that now, appropriately, carries Alzheimer’s name.

**Pathogenesis** Careful analyses of the “senile” plaques and neuronal fibrillary changes have been made in the last few decades in an attempt to elucidate the mechanism of Alzheimer disease. Several histologic techniques assist in this endeavor, including refined methods for silver impregnation that stain both amyloid and its main constituent (amyloid β protein, or Aβ); immunostaining using antibodies specific to such proteins as ubiquitin, neuronal tau protein, and amyloid β protein; and visualization of beta-pleated protein sheets using thioflavine S and Congo red with ultraviolet and polarized light. Tau is a discrete cytoskeletal protein that promotes the assembly of microtubules, stabilizes their structure, and participates in synaptic plasticity in a yet to be defined manner. In the pathologic circumstances of Alzheimer disease, progressive supranuclear palsy, and frontotemporal dementia (see further on), tau is hyperphosphorylated and aggregates, resulting in an overloaded of the perikarya and neurites with paired helical filaments comprising neurofibrillary tangles. Electrophoretically, tau moves with the β-2-globulins and is thought to function as a transferrin, i.e., it binds iron and delivers it to the cell. Its concentration can be measured in the CSF and serum, but this has not yet proven to be useful as a diagnostic test.

The Aβ protein is a small portion of a larger entity, the amyloid-protein precursor (APP), which is normally bound to neuronal membranes. As shown in Fig. 39-2, the Aβ protein is cleaved from APP by the action of proteases termed α, β, and γ secretase. One current hypothesis, developed by Selkoe and others, focuses on the manner in which APP is cleaved by these enzymes to give rise to different-length residues of Aβ. During normal cellular metabolism, APP is cleaved by either α or β secretase. The products are then cleaved by the γ isoform. The sequential cleavage by α and then γ produces tiny fragments that are not toxic to neurons. However, sequential cleavage by β and then γ results in a 40–42 amino acid product, Aβ40, and a longer 42–40 amino acid form. The latter Aβ42 form is toxic in several models of Alzheimer disease. The presenilins interact with or may be a component of γ secretase, the enzyme that produces the Aβ42 fragment. Mutations of presenilin 1 and 2 also increase the relative levels of Aβ42. It should be noted that mutations of the APP and presenilin genes explain fewer than 0.1 percent of Alzheimer cases (Terry). Transgenic mice that express human Alzheimer disease–associated mutations in APP or presenilin genes develop plaques with Aβ42 but not neurofibrillary tangles. There is also a provocative relationship between certain circulating proteins, particularly β-amyloid and selected isoforms of the ApoE lipoproteins, as discussed further on. The current notions of amyloid metabolism and the role of Aβ are summarized in Fig. 39-2. Many of the relationships and mechanisms depicted in the figure are derived from the understanding of genetic forms of Alzheimer disease; the extent to which they will be implicated in the idiopathic disease is not known. However, some form of disruption in these mechanisms are likely be involved in the sporadic disease.

---

**Figure 39-2.** Diagram of proteolysis of amyloid precursor protein (APP). When APP is cleaved sequentially by β secretase and then γ secretase, the resulting amyloid protein can be 40 (Aβ40) or 42 (Aβ42) amino acids in length. The latter favors the formation of aggregated fibrillary amyloid protein (fibrillogenesis) rather than normal APP degradation. The fibrillary form of amyloid is neurotoxic, a mechanism favored as the cause of cell damage in Alzheimer disease. Formation of Aβ42 is promoted by mutations, either in the APP gene itself or in the presenilins. In Down syndrome, excess production of APP and its product Aβ42 is caused by triplication of the long arm of chromosome 21, the location of the APP gene. The ApoE4 allele is associated with inadequate clearance of Aβ42 and is another mechanism that promotes fibrillogenesis. (Modified by permission from Sisodia SS, St. George–Hyslop PH: γ-Secretase, notch, Aβ and Alzheimer’s disease: Where do the presenilins fit in? Nat Rev Neurosci 3:281–290, 2002.)
It must be emphasized, however, that there is some uncertainty regarding the relationship of amyloid deposition to the loss of neurons and brain atrophy. In their review, Hardy and Selkoe, authoritative investigators in this field, have pointed out that “Although the amyloid hypothesis offers a broad framework to explain AD pathogenesis, it is currently lacking in detail, and certain observations do not fit easily with the simplest version of the hypothesis.” They also emphasize that soluble oligomers of Aβ amyloid may be the toxic agents, whereas the emphasis until now has been on the effects of visible assemblies of insoluble amyloid fibrils. Others too have questioned the amyloid hypothesis and pointed to an imprecise relationship between amyloid deposition and neuronal loss, even suggesting that amyloid is in some way a protective mechanism of cells.

The finding of a reduced number and enlargement of synapses in affected cortex early in the disease by DeKosky and Scheff and others could be interpreted as either the first sign of neuronal death or the result of the neuronal loss. Amyloid deposition would then be a later, secondary phenomenon. The importance of neurofibrillary tangles has also been questioned, and the manner in which amyloid deposition relates to tangle formation is unclear. Unexplained also is prominent senile plaque formation in some cases and neurofibrillary tangles in others. One prevalent view is that the tangles are a secondary phenomenon. Nonetheless, the amyloid hypothesis is currently the strongest. In recent years, some of the subcellular mechanisms that are deranged by the presence of intracellular or extracellular amyloid have been elucidated. These are too complex and uncertain to list here, but they are among the most promising findings in this field of research.

It has been our view that vascular changes do not have an important role in the pathogenesis of Alzheimer disease, but several groups hold a different opinion. It was long ago established that Alzheimer disease is not caused by any of the usual types of arteriosclerosis. There are, however, small-vessel changes, accounting for the reduced cerebral blood flow reported in many cases of the disease. This small-vessel change is probably secondary to the cerebral atrophy, since a reduction in cerebral blood flow is found in mentally intact old individuals. Probably the deposition of amyloid in cerebral vessels is a secondary phenomenon as well. On the other hand, several studies have indicated that the presence of cerebral infarctions, small or large, may accelerate the deposition of amyloid and the development of neurofibrillary tangles in the brains of Alzheimer patients (see further on, under “Vascular Dementia”). Not surprisingly, cerebrovascular disease also exaggerates the rate of progression and degree of dementia. How this relates to the ill-defined entity called “arteriosclerotic,” “multi-infarct,” or “vascular” dementia has not been clear to the authors (see pages 373 and 707). A similar relationship between Alzheimer disease and previous head injuries is even more tentative but has led to speculation that several types of brain injury are conducive to the development of Alzheimer change and amyloid deposition, as if they were part of a reparative response.

No relationship to premorbid personality traits earlier in life has been established, but an intriguing finding from what has become known as the “nun study” suggests that poor linguistic ability early in life may correspond to the later development of Alzheimer disease (D. A. Snowden et al). In this study, the autobiographies of 93 nuns, written in their twenties, were rated for linguistic and ideational complexity. Of 14 sisters who died in late life, deterioration of cognitive function and neuropathologically proven Alzheimer disease occurred in 7 who had a low “idea density” in their writings and in none of 7 whose writings were cognitively more complex. Obviously this type of correlation requires further study and is subject to several interpretations. Also, there has been a general notion, confirmed by a few studies such as the one by Verghese et al, that an active mental life may reduce the severity of mental decline with aging; but a direct conclusion about Alzheimer disease cannot be made from the available information.

Neurotransmitter Abnormalities Considerable interest was created in the late 1970s by the finding of a marked reduction in choline acetyltransferase (ChAT) and acetylcholine in the hippocampus and neocortex of patients with Alzheimer disease. This loss of cholinergic synthetic capacity was attributed to the loss of cells in the basal forebrain nuclei (mainly the nucleus basalis of Meynert), from which the major portion of neocortical cholinergic terminals originate (Whitehouse et al). As is often true in medical science, the early enthusiasm for the cholinergic hypothesis has obtained less support from subsequent research. A 50 percent reduction in ChAT activity has been found in regions such as the caudate nucleus, which show neither plaques nor tangles (see review of Selkoe). The specificity of the nucleus basalis-cholinergic-cortical changes was questioned for other reasons as well. The Alzheimer brain also shows a loss of monoaminergic neurons and a diminution of noradrenergic, GABA-ergic, and serotonergic functions in the affected neocortex. The concentration of amino acid transmitters, particularly of glutamate, is also reduced in cortical and subcortical areas (Sasaki et al). The Alzheimer cortex shows a decreased concentration of several neuropeptide transmitters—naturally substance P, somatostatin, and cholecystokinin—but it has not been determined whether any of these biochemical abnormalities, including the cholinergic ones, are primary or are secondary to heterogeneous neuronal loss. Finally, the administration of cholinomimetics—whether they be acetylcholine precursors (e.g., choline or lecithin), degradation inhibitors (e.g., physostigmine), or muscarinic agonists that act directly on postsynaptic receptors—have had only a mild and unsustainable therapeutic effect (see further on under “Treatment”).

Chase and associates have demonstrated a 30 percent reduction in cerebral glucose metabolism in Alzheimer disease, greatest in the parietal lobes, but again the meaning of this, whether it is due to loss or to hypofunction of neurons, remains to be determined. It seems most likely to be secondary to tissue loss in these regions. The significance of aluminum in the genesis of neurofibrillary tangles, as was once proposed, has never been validated. Recently it has been suggested that the use of estrogen by postmenopausal women delays the onset of the disease and might reduce its frequency, but this has not been corroborated by subsequent studies.

Genetic Aspects of Alzheimer Disease (Table 39-1) Of great interest and potential importance was the aforementioned discovery, in patients with an inherited form of Alzheimer disease, of a defective gene that codes for an errant amyloid precursor protein (APP) and is localized to a region of chromosome 21, near the β-amyloid gene (St. George-Hyslop et al). This also provides an explanation for the Alzheimer changes that characterize the brains of practically all patients with the trisomy 21 defect (Down syndrome) who survive beyond their 20th year; they overproduce amyloid as a result of the triplication of the gene. But gene defects on chromosome 21, as already noted, are responsible for only a small proportion of familial cases and a miniscule percentage of disease overall. Other kindreds with familial Alzheimer disease have been linked to rare mutations of the presenilin genes on chromosome 14.

AD = autosomal dominant.

(presenilin 1, Sherrington et al), accounting in some series for up to 50 percent of familial cases, and on chromosome 1 (presenilin 2), which may account for many of the remaining ones (Levy-Lahad et al). These are summarized in Table 39-1. The age of onset of the disease in these familial forms, as in the Down cases, is earlier than that in sporadic forms. Notable is the common occurrence of asynchronous myoclonus, epilepsy, aphasia, and paratonia in the familial cases.

It has been clear for some time that an excess amyloid alone is an incomplete explanation for the disease. Apolipoprotein E (ApoE), a regulator of lipid metabolism that has an affinity for the β-amyloid protein in Alzheimer plaques, has been found to be another genetic marker that greatly modifies the risk of acquiring Alzheimer disease. Of the several isoforms of ApoE, the presence of E4 (and its corresponding gene allele e4 on chromosome 19) is associated with a tripling of the risk of developing sporadic Alzheimer disease (Roses, Strittmatter et al, and Polvikoski et al). This is the same allele that contributes to an elevated low-density lipoprotein fraction in the serum. Possession of two e4 alleles virtually assures the development of disease in those who survive to their eighties. The e4 allele also modifies the age of onset of some of the familial forms of the disease. In contrast, the e2 allele is underrepresented among Alzheimer patients. For these reasons it has been proposed that ApoE, by interacting with APP or tau protein in some way, modifies the formation of plaques. Indeed, possession of the e4 allele correlates with increased deposition of Aβ in the brain (McNamara). Furthermore, as pointed out by Hardy, ApoE appears to act after the various genetic mutations have influenced the cell dysfunction that causes Alzheimer disease. These findings have led to interest in using the e4 genotype as a marker for the risk of Alzheimer disease, but it must be pointed out that these are statistical relationships that do not invariably connect the allele to the disease in a particular individual. In other words, the e4 allele does not act as a mendelian trait but as a susceptibility (risk) factor. It follows that many individuals without the allele also develop Alzheimer disease. Moreover, many individuals with the e4 allele live into their seventies and eighties without developing Alzheimer disease. Therefore the results of such testing must be interpreted with caution. All that can be stated with certainty is that, on average, the presence of the e4 allele accelerates the appearance of Alzheimer disease by about 5 years.

Studies of the molecular genetics of Alzheimer disease are yielding new information at such an astonishing rate that much of the foregoing will soon be outdated. Useful basic reviews of this subject are those of Martin and of Selkoe, listed in the References.

Diagnostic Studies The most useful, but not definitive, ancillary tests in use are CT scanning and MRI (Fig. 39-3). In patients with advanced Alzheimer disease, the lateral and third ventricles are enlarged to about twice normal size and the cerebral sulci are widened. As stated previously, fine-section coronal MRI of the medial temporal lobes reveals a disproportionate atrophy of the hippocampi and a corresponding enlargement of the temporal horns of the lateral ventricles. Early in the disease, however, the changes do not exceed those found in many mentally intact old persons. For this reason, one cannot rely on imaging procedures alone for diagnosis. CT and MRI scans are most valuable in excluding brain tumor, subdural hematoma, cerebral infarction, and hydrocephalus. The EEG undergoes a diffuse slowing, but only late in the course of the illness. The CSF is also normal, though occasionally the total protein is slightly elevated. Using the constellation of clinical data, CT scanning, and MRI—along with the age of the patient and time course of the disease—the diagnosis of senile dementia of Alzheimer type is being made correctly in 85 to 90 percent of cases.

Of some value in our experience have been studies of cerebral blood flow (single-photon emission tomography, or SPECT) and metabolism (positron emission tomography, or PET), which show diminished activity in the medial temporal lobes, sometimes early in the disease. Nevertheless, in most cases, when such changes were evident, the diagnosis was already obvious on clinical grounds alone. Our recent experience has been that the pattern of Alzheimer change on these blood flow and metabolic studies is too often applied indiscriminately.

Neuropsychologic tests show deterioration in memory and verbal access skills. Testing is particularly useful when there is a serial decline in ability. The use of these examinations is described in Chap. 21. Certain aspects of attention and executive function in Alzheimer disease have recently been reviewed by Perry and Hodges.

There is no firm biologic marker of Alzheimer disease with the exception of an imprecise association with the disease-modifying e4 apolipoprotein allele, as mentioned earlier. The ratio of Aβ to tau in the cerebrospinal fluid (curiously low in Alzheimer disease) has been proposed as a useful test, but is not yet well enough validated for routine use (Maddalena et al).

Differential Diagnosis (See also Table 21-3, page 374) Formerly, when virtually all forms of presenile and senile dementia were untreatable, there was little advantage to either the patient or the family in ascertaining the cause of the cerebral disease. Such patients were customarily left at home or committed to an institu-
mentia of AIDS and paraneoplastic limbic encephalitis may be partially amenable to treatment. Exclusion of these several diseases is most readily accomplished by sequential outpatient evaluations or by a brief admission to a hospital, where examinations of blood and CSF, EEG, CT, MRI, and neuropsychologic testing can be undertaken.

One of the problems in differential diagnosis, in the authors’ experience, has been the distinction between a late-life depression and a dementia, especially when some degree of both are present. Observation over several weeks or more, and the patient’s demeanor, makes the distinction obvious. Multi-infarct dementia is not difficult to separate from Alzheimer dementia, but patients with the latter illness may have had one or more clinically inapparent infarcts as discussed further on. The dementia of normal-pressure hydrocephalus may also be confused with Alzheimer dementia (page 535). The problem of distinguishing Alzheimer disease from a more “benign” form of memory decline associated with aging comes up frequently in practice, as discussed on page 370. The differential diagnosis of these several treatable conditions is discussed in Chaps. 21, 30, 34, and 49. From time to time, we have been confident on clinical grounds that a patient had Alzheimer disease, only to have revealed at autopsy that progressive supranuclear palsy, Lewy body disease, Pick disease another non-Alzheimer degeneration of the frontal lobes, or cortical-basal ganglionic degeneration was the cause, as noted below. All of these are discussed later in this chapter.

Treatment There is little evidence that any of the proposed forms of therapy for Alzheimer disease—cerebral vasodilators, stimulants, l-dopa, massive doses of vitamins B, C, and E, and many others—has any salutary effect. Trials of oral physostigmine, choline, and lecithin have yielded mostly negative or uninterpretable results, and the evidence favoring the currently popular cholinergic precursors and agonists and acetylcholinesterase inhibitors, such as tacrine and donepezil, is only modest. With regard to the latter group of drugs, most large trials have demonstrated a slight prolongation of the patient’s ability to sustain an independent life, but such evidence generally requires that the medications be taken for 6 to 12 months. The salutary effects on memory are harder to document; nonetheless, despite some trials that have failed to demonstrate benefit (c.f., AD 2000 Collaborative Group), the balance of evidence may favor the use of these medications. Side effects may include nausea or diarrhea in a small number of patients. We have been unable to interpret the few reports from the families of our patients that the medication caused insomnia or increased confusion. It is worth mentioning that when the acetylcholine receptor antagonist succinylcholine is used prior to general anesthesia, its effects may be prolonged in patients taking the above drugs. The use of trazodone, haloperidol, thioridazine, risperidone, and related drugs may suppress some of the aberrant behavior and hallucinations when these are problems, making life more comfortable for both patient and family. Small doses of diazepines, such as lorazepam, are useful when sleep is severely disturbed.

The N-methyl-D-aspartate (NMDA) glutaminergic antagonists, specifically memantine (20 mg daily) have also been tried. In a study of memantine by Reisberg and colleagues of 252 patients (187 of whom completed the trial), there were better results on a few scales that reflect functional behavior compared to the use of placebo, but there was no change in three measures of cognitive performance. The side effects were minor and this drug has now been approved for use in late-stage Alzheimer disease. As a result,

mementine is now being applied more widely, particularly in later stages of the disease and in conjunction with cholinergic drugs.

A provocative series of animal experiments that demonstrated the possibility of removal of plaques by immunization against amyloid has led to human studies with a similar vaccination. One trial has been stopped because of the occurrence of an immune encephalitis induced by the treatment in a few patients, but in autopsy material there were indications that the treatment may have had the desired effect. Revised vaccines are being formulated for further testing of this novel approach.

Perhaps more important than the use of any drugs is the general management of the demented patient, which should proceed along the lines outlined in Chap. 21, keeping in mind that the physician’s counsel is often the family’s main resource for medical and social decisions.

**Associated Pathologic States** As indicated earlier, the histologic changes of Alzheimer disease have a number of interesting associations. The changes are far more common in the brains of patients with Parkinson disease than in the brains of age-matched controls (Hakim and Mathieson). These findings at least partly explain the high incidence of dementia in patients with Parkinson disease (see further on, in the sections regarding Parkinson disease and Lewy body dementia), yet not more than 20 to 30 percent of patients with Parkinson disease have plaques and tangles. Another association between the two diseases is apparent in the *Guamanian Parkinson-dementia complex*, which is also discussed below. In this entity, the symptoms of dementia and parkinsonism are related to neurofibrillary changes in the cerebral cortex and substantia nigra, respectively; senile plaques and Lewy bodies are unusual findings.

Alzheimer disease in relation to the Down syndrome, first noted and reported by Jervis, is now widely recognized. The characteristic plaques and neurofibrillary tangles appear in the third decade; they increase with age and are present in practically all patients with the Down syndrome after 40 years of age. The basis for excess amyloid production in Down syndrome was discussed earlier.

There are rare instances, such as those reported by Malamud and Lowenberg and by Loken and Cyvin, in which dementia begins in late childhood, with the finding at postmortem examination of the typical Alzheimer lesions in the cerebral cortex and basal ganglia. The clinical picture in these juvenile and early adult cases has been more varied than in the older ones. In some, paucity of speech, gait ataxia, and pyramidal and cerebellar signs leading to inability to stand or walk have appeared at various stages of the disease.

The finding of neurofibrillary changes (and to a lesser extent plaques) in boxers ("punch-drunk syndrome", or "dementia pugilistica") is another interesting ramification of the Alzheimer disease process (page 863). Hydrocephalus is present also, but there is insufficient information to determine whether this is due to a normal-pressure tension hydrocephalus from multiple subarachnoid hemorrhages or a hydrocephalus ex vacuo from cerebral atrophy.

Similarly, some cases of what has come to be called “primary progressive aphasia” (see page 908) have Alzheimer change and amyloid plaque deposition as the primary pathologic change. A close relationship between Pick, Alzheimer, and Parkinson diseases has been demonstrated in a large family with dysphasic dementia (Morris et al.). Other isolated combinations, wherein Alzheimer disease, hypothyroidism, hypopituitarism, or neurosyphilis were conjoined, were probably a matter of chance and prove nothing. From time to time other unusual associations come to light, such as dementia with motor neuron disease or the cases of familial dementia with spastic paraplegia reported by Worster-Drought and by van Bogaert and their associates (see further on in this chapter). Here, neurofibrillary change is the most prominent feature while amyloid plaques are negligible in number or absent.

**Lobar Atrophies (Pick Disease and Frontotemporal Dementia)**

In 1892, Arnold Pick of Prague first described a special form of cerebral degeneration in which the atrophy is circumscribed (most often in the frontal and/or temporal lobes), with involvement of both gray and white matter—hence the term *lobar* rather than *cortical* sclerosis. In 1911, Alzheimer presented the first careful study of the microscopic changes. The most complete analyses of the pathologic changes until recently have been those of Spatz, van Mansvelt, Morris and coworkers, and Tissot and associates. The nosology of the lobar atrophies has become extremely confusing over the past decade. It has become clear that the pathologic change associated with neuronal loss in this category of disease may be any one of several types: lobar atrophy with Pick inclusion bodies, with neurofibrillary tangles, with other inclusions, or no characteristic changes. Furthermore, gliosis and mild spongiform changes in the superficial layers of cortex, and even typical Alzheimer plaque and tangle pathology, have all been associated with syndromes and gross pathologic atrophy of the frontal and/or temporal lobes. Confusion has arisen because these illnesses have been denominated either by the clinical syndrome that derives from a particular region of atrophy or by the pathologic change. Several terms have been applied to various forms of lobar atrophy, *frontotemporal dementia* being the most common (see below). Nonetheless, among these, fairly distinct clinicopathologic syndromes of Pick disease and of frontotemporal dementia are recognizable.

Since the recognition of Pick disease rests more on pathologic than on clinical criteria, this is described first. In contrast to Alzheimer disease, in which the atrophy is relatively mild and diffuse, the pathologic change in lobar atrophy is more circumscribed and sometimes asymmetrical. The atrophy may extend to the island of Reil and the amygdaloid-hippocampal structures. The parietal lobes are involved less frequently than the frontal and temporal lobes. The affected gyri become paper-thin, resembling the kernel of a dried walnut. The cut surface reveals not only a marked narrowing of the cortical ribbon but a grayish appearance and reduced volume of the underlying white matter. The corpus callosum and anterior commissure share in the atrophy. The overlying pia-arachnoid is thickened, and the ventricles are enlarged. The pre- and postcentral, superior temporal, and occipital convolutions are relatively unaffected and stand out in striking contrast to the wasted parts. Pick insisted that the disease essentially involves the association areas of Flechsig, but this is not always so. In some instances, atrophy of the caudate nuclei has been pronounced, almost to the degree seen in Huntington chorea. The thalamus, subthalamic nucleus, substantia nigra, and globus pallidus may also be affected, but only to a slight degree.

The salient histologic feature of Pick disease is a loss of neurons, most marked in the first three cortical layers. Surviving neurons are often swollen, and some contain argyrophilic (Pick) bodies within the cytoplasm. Ultrastructurally, the Pick bodies are made up of straight fibrils, thus differing from the paired helical filaments that characterize Alzheimer disease. These bodies predominate in the medial parts of the temporal lobes, especially in the atrophic hippocampi. “Ballooning” of cortical neurons is found...
mainly in the frontal cortex, and in such cases, according to Tissot and others, atrophy of the basal ganglia and substantia nigra is especially frequent and severe. There is a loss of myelinated fibers in the white matter beneath the atrophic cortex. A heavy astrocytic gliosis is seen in both the cortex and subcortical white matter. Most neuropathologists consider the loss of myelinated fibers in the white matter, basal ganglia, and thalamus to be consequent to neuronal loss in the cortex. Senile plaques and Alzheimer neurofibrillary changes are seen in the atrophic zones in some of the cases, as alluded to earlier, and there is granulovacuolar degeneration of neurons in the hippocampus, but not to the degree seen in Alzheimer disease.

It is the lobar atrophy and marked changes in the underlying white matter that provide the unifying elements of all the lobar atrophies. These changes are readily appreciated by CT scanning and MRI in advanced cases.

**Clinical Features** Whether the diagnosis of Pick disease can be made consistently on purely clinical grounds is doubtful. Our predictions as to the existence of the pathologic changes and their differentiation from those of Alzheimer disease and the more recently defined entity of “frontotemporal dementia” (described below) have been erratic, although they should improve with experience and proper use of CT and MRI (particularly coronal MR images). Sometimes the imaging features of unilateral or bilateral lobar tissue loss are so prominent as to almost oblige the diagnosis of lobar atrophy. In our experience, the gradual onset of mental confusion with respect to place and time, anoma, slowness of comprehension, inability to cope with unaccustomed problems, loss of tact, deterioration of work habits, neglect of personal hygiene and grooming, apathy, and alterations of personality and behavior have been prominent features. In addition to these personality changes, an inability to perform sequences of motor tasks, motor perseveration, apathy (emotional indifference), inattention, abulia, impairment of gait and upright stance, and prominent grasp and suck reflexes are attributable to predominant affection of the frontal lobes. Bulimia and alterations in sexual behavior occur to a distressing degree in some patients (Tissot et al).

The similarities to the clinical entity of frontotemporal dementia described below is apparent. In part for this reason, the notion of a “Pick complex” has been suggested, encompassing lobar atrophy with Pick bodies, frontotemporal dementia, and other entities in which tau depositions are prominent, such as corticobasal degeneration, primary progressive aphasia, and progressive supranuclear palsy. In keeping with the basic approach of the book, we still prefer to separate these entities when they are clinically distinct, only remarking that several pathologies may give rise to each of these states. The location of the neuronal degeneration is the main determinant of the clinical presentation.

Wilson distinguished two patterns of abnormal behavior: in one, the patient is talkative, lighthearted, cheerful or anxious, constantly on the move, occupied with trifles, and attentive to every passing incident; in the other, the patient is taciturn, inert, emotionally dull, and lacking in initiative and impulse. Probably these two patterns represent predominantly temporal and frontal types, respectively. According to Tissot and colleagues, the frontal, temporal, and parietal lobes are all affected in 75 percent of patients by the time the disease terminates.

The cause of Pick disease is unknown. While most cases are sporadic, Sjögren and associates concluded from a genetic survey of the cases in Stockholm that Pick disease may be transmitted as a dominant trait with polygenic modification. Such a Dutch family with almost 100 percent penetrance over several generations has been reported by Schenk. Women seem to be affected more often than men. No chemical, vascular, traumatic, or other factor of possible causal importance has been identified.

The course of the illness is usually 2 to 5 years, occasionally longer, and nothing can be done therapeutically except to postpone the end by careful nursing.

**Frontotemporal Dementia**

(See also page 372)

This descriptive term has been used by neurologists and neuropathologists to refer to a dementia that is associated with degeneration of the frontal and temporal lobes. Many such instances have proved to be examples of Alzheimer disease and, in lesser numbers, Pick disease, as noted above. Also, for many years neuropathologists have been aware of instances of dementia that are identical clinically and in their gross pathology (severe gyral atrophy) to the Alzheimer and Pick types but do not show the characteristic histologic changes of either of these diseases. They do, however, exhibit tau-staining material in neurons of the affected regions. In some cases, this is attributable to mutations in the gene on chromosome 17 that encodes the tau protein. These mutations alter the proportions of different forms of this protein and lead both to tau accumulation and its hyperphosphorylation. Indeed, many cases of frontotemporal dementia are associated with tau gene mutations (Basun et al). However, it is important to note that abnormal aggregates of tau have been identified in practically all neurodegenerative atrophies and, of course, form the main constituent of the paired helical filaments (neurofibrillary tangles) of Alzheimer disease, and they are abundant, although of slightly different structure, in progressive supranuclear palsy. From the observations of Brun and of Neary and their associates, pure tau-reactive cases actually outnumber Pick disease when the latter is strictly defined by the cortical white matter degeneration and Pick inclusions, but the distinctions between the two have not always been clear from writings on the subject.

Some of the clinical aspects of frontotemporal dementia are discussed in Chap. 21, but, broadly speaking, the patients under consideration present the personality and behavioral abnormalities that would be expected from frontal and anterior temporal lobe dysfunction, much as described earlier for Pick disease, including apathy, perseveration, poor judgment and abstraction, bizarre affect, and a general disengagement. Insight is almost always impaired, and some subjects become euphoric or display repetitive compulsive behaviors. An initial diagnosis of depression has been common on our services. Other psychiatric symptoms—such as sociopathic and disinhibited behavior with aspects of hyperorality and hyperphagia—may predominate. (All of Wilson’s comments, noted above in relation to Pick disease, pertain here as well.) Alternatively, aphasic or word-finding syndrome corresponding to a lateral temporal lobe degeneration may be the initial presenting and predominant feature, sometimes for several years, before other manifestations of dementia become evident. A proportion of patients have parkinsonian features, but this should always raise the question of corticobasal-ganglionic degeneration (see further on). Motor neuron disease is also linked to frontotemporal dementia in a small number of cases. This is particularly the case in the Gamanian (now called western Pacific) variety and in the heredofamilial frontotemporal atrophy linked to a mutation on chromosome 17.
In recent writings on this subject, the term frontotemporal dementia has come to be used in a highly restricted sense, being arbitrarily assigned to cases that show only tau-staining material in neurons. Most of the cases are sporadic, but the inherited variety linked to chromosome 17, in which parkinsonism is prominent, supports its distinction as a separate entity; it is in these cases that the intraneural deposition of tau is most striking, in both the frontotemporal cortex and the substantia nigra.

Noteworthy also is the observation that a dementia identical to that of the tau-reactive cases has been observed in others without any tau staining of neurons. Also, some of the frontally predominant cases have shown only marked vacuolation (microcavitation) of the affected cortex; cases of the latter type have been described in patients with ALS (where tau staining has reportedly been found in the anterior horn cells). In such cases, amyloid plaques and neurofibrillary tangles are no more abundant than expected for the age of the patient.

In sum, the relationship between Pick disease and frontotemporal dementia is still uncertain, hence the appeal of the term Pick complex. The clinical and gross pathologic findings— a regional frontotemporal atrophy of the cerebrum, bilateral or unilateral—are nearly identical in the two disorders. The main distinction is the presence or absence of Pick bodies or tau-staining material in neurons of the affected regions and greater affection of the white matter in Pick disease. If indeed the Pick and tau inclusions are shown in the future to specify distinctive biologic types, they can be considered to represent separate diseases. A measure of the confusion among experts in the field is reflected in the monograph by Kertesz, in which votes were taken regarding various terminologies and opinion was considerably divided.

**Primary Progressive Aphasia**
(See also page 906)

Focal disturbances, particularly aphasia and apraxia, occur early and prominently in certain patients with Pick-like lobar atrophy, indicating a lesion in the left frontal and/or temporal lobes. Viewed from another perspective, a language disorder has been described in two-thirds of all patients with temporal lobe atrophy. At first, the patient speaks less and has word-finding difficulty (anomia), but language structure is intact (Mesulam); later, he may forget and misuse words and soon fails to understand much of what is heard or read. Speech becomes a “medley of disconnected words and phrases” and eventually is reduced to an incomprehensible jargon. Later, dysarthria and apraxia become apparent, and finally, the patient is mute, seemingly without impulse to speak, with a complete loss of the ability to form words (Snowden et al). In a less common form, there is early comprehension difficulty followed by verbal perseveration, but fluency is retained. The above descriptions conform also to what is now called primary progressive aphasia, and it is notable that, according to Mesulam, who has studied the condition extensively, 60 percent of these cases show no characteristic pathologic change, 20 percent have Pick bodies, and a similar proportion show the typical changes of Alzheimer disease in the affected cortical region. A familial tendency has not been found.

**Lewy Body Dementia**

Next to Alzheimer disease, diffuse Lewy body disease, or Lewy body dementia, has been the most frequent pathologic diagnosis established in most series of demented patients. Reports of this condition have been increasing steadily since the original communication by Okazaki and others in 1961 (see review by Kosaka). The disease is marked by parkinsonian features, dementia, and a frequent tendency to episodic delirium, as described below. The syndrome may be clinically indistinguishable from Alzheimer disease, but it is defined by diffuse involvement of cortical neurons with Lewy body inclusions and by an absence or inconspicuous number of neurofibrillary tangles and senile plaques. To some extent increased recognition of this disorder is due to improved histologic techniques, particularly the ability to detect ubiquitin by immunostaining and, more recently, similar stains for synuclein, which enable one to visualize Lewy bodies in the cerebral cortex more clearly than had been possible in the past. Because the Lewy bodies in cortical neurons are not surrounded by a distinct halo, as they are in the substantia nigra in cases of Parkinson disease, they were not readily appreciated until the development of these antibody stains. The fact that aggregated α-synuclein is the main component of the Lewy body will undoubtedly prove important in understanding both Parkinson disease and Lewy body dementia.

**Clinical Features**

Burkhardt and colleagues, in an analysis of 34 cases of diffuse Lewy body disease, found that the characteristic syndrome was one of progressive dementia in an elderly patient with the late onset of parkinsonian signs in some cases. For this reason, the disease also properly belongs in the category of dementias that are accompanied by other prominent neurologic features (page 897). Difficulty in diagnosis arises because the movement disorder may be either mild or prominent and may occur as an early or a late manifestation. In Lennox’s summary of 75 cases published up to 1990, parkinsonism, and particularly a limb and axial rigidity, was a prominent feature in 90 percent once the illness was fully developed, and almost half had tremor of the Parkinson type.

The parkinsonian features may respond favorably to L-dopa, but only for a limited time and sometimes at the expense of delirium or hallucinations that would be characteristic of early idiopathic Parkinson disease (Hely et al); in others, the response to L-dopa is not as consistent. Some patients also have orthostatic hypotension corresponding to cell loss and Lewy bodies in the intermediolateral cell column of the spinal cord or in the sympathetic ganglia, thereby simulating striatonigral degeneration or Shy-Drager syndrome (see further on).

Byrne and associates pointed out that episodic confusion, hallucinations, and paranoid delusions were a feature of the Lewy body dementia; such psychotic features are generally uncharacteristic of Alzheimer and lobar dementias. In Lennox’s review, one-third of patients had these swings in behavior, but as the illness advanced, the amnesia, dyscalculia, visuospatial disorientation, aphasia, and apraxia did not differ from those of Alzheimer disease. In the cases reported by Fearnley and coworkers, there was a supranuclear gaze palsy simulating that of progressive supranuclear palsy.

In our experience with Lewy body disease, the parkinsonian symptoms have been more prominent than in progressive supranuclear palsy, and the most characteristic feature besides the movement disorder and a slowly advancing dementia has been a vacuous anxious state with intermittent psychotic or delirious behavior. Others have commented on an extreme sensitivity of such patients to neuroleptic drugs, including increased confusion and greatly worsening parkinsonism or the development of the neuroleptic malignant syndrome.
With regard to diagnostic testing, only the finding of reduced activity in the posterior parietal cortical regions on PET scans has been found as a relatively consistent but not invariable feature.

**Other Degenerative Dementias**

**Diffuse Cerebral Atrophy of Non-Alzheimer Type** There are other forms of progressive, diffuse brain atrophy leading to dementia that show none of the pathologic features of either Alzheimer or Pick disease or any of the other diseases sometimes associated with a dementing illness (i.e., frontotemporal, Parkinson or Lewy body disease, ALS, and progressive supranuclear palsy).

In Sweden, for example, Sjögren has found familial cases of this type, as have Schaumburg and Suzuki in this country, and we have seen several sporadic examples. The clinical picture in these cases has been indistinguishable or has varied only slightly from that of Alzheimer disease, and autopsy has disclosed widespread cerebral atrophy, most pronounced in the frontal lobes. Microscopically these cases are characterized by a diffuse neuronal loss, slight glial proliferation, and similarly slight secondary alteration of the white matter. Other instances of sporadic and familial presenile dementia have shown subcortical gliosis or nonspecific cellular changes (atrophy of nerve cells and nuclei, loss of Nissl substance). Some examples of the latter type have in the past been described under the rubric of “Kraepelin disease” and more recently as “dementia lacking distinctive histologic features” (Knopman et al). Perhaps some of these cases will turn out to be a variant of the “tau” form of frontotemporal dementia, as discussed above. Notable is the presence of this same nondescript pathologic change in some cases of leobar atrophy, particularly primary progressive aphasia.

**Argyrophilic Grain Disease** This obscure entity has been connected with a late-life dementia in which behavioral disturbances precede memory difficulty. Whether the finding of argyrophilic grains in the mediotemporal lobe, different from tau-laden neurofibrillary tangles and from the glial inclusions (putatively a defining feature of multiple system atrophy), constitutes a specific entity is not clear to the authors. Probst and Tolnay remark that these argyrophilic grains are not found in nondemented individuals. It is not likely that the condition can be identified in life; if it is a genuine entity, it must be rare.

**Thalamic Dementia** A relatively pure degeneration of thalamic neurons is described from time to time in relation to a progressive dementia, but it must also be rare (Stern; Schulman). Reported cases have evolved rapidly (several months) and have been associated in some instances with choreoathetosis. Garcin and colleagues described five such instances of subacute developing dementia, which they considered initially to be examples of Creutzfeldt-Jakob disease. In each of them the pathologic changes consisted primarily of neuronal loss and gliosis of the thalamus. A large kindred characterized by subacute dementia and myoclonus and inherited as an autosomal trait, has been reported by Little and coworkers. In members of this family, the clinical presentation was also very similar to that of Creutzfeldt-Jakob disease; however, the pathologic changes were confined to the thalamus, particularly to the mediodorsal and other anterior and medial thalamic nuclei. Transmission of the disease to primates was unsuccessful. We raise the question if some of these cases were unappreciated instances of cerebral deep venous thrombosis, late-onset Leigh disease (sub-acute necrotizing encephalopathy), or even more unusual conditions such as fatal familial insomnia.

**Neuroserpinopathy** In recent years, there have been case reports of dominantly inherited, adult-onset dementia with a fulminant evolution suggestive of encephalopathy and the special feature of seizures. As distinctive as this combination of dementia and seizures has been the presence at autopsy of large eosinophilic, PAS-positive intraneuronal inclusions that contain aggregates of neuroserpin, thus the initial description under “familial encephalopathy with neuronal inclusion bodies.” The serpins are a family of protease inhibitors that include neuroserpine, a protein expressed exclusively in neurons. The neuronal inclusions are densest in the deep layers of the cortex and in the substantia nigra. Missense mutations in the gene encoding neuroserpin have been identified as the cause. This newly described disease is reviewed by Lomas and Carrell.

**Vascular Dementia** Finally, a comment is required regarding the group of diseases popularly called “vascular dementia” and listed in many classifications as among the most common causes of chronic mental deterioration, second only to Alzheimer disease. One might remember that in past decades, much of senile dementia was incorrectly attributed to “cerebral atherosclerosis.” Without doubt, as discussed in Chap. 34, multiple cerebral strokes may cause increasing deficits that cumulatively qualify as a dementia, but at least some of the focal lesions that contribute to the cognitive worsening in the clinical syndrome can be identified, and there is a corresponding stepwise decline. Admittedly, this type of vascular dementia may be more difficult to recognize when a number of the infarcts are of the relatively silent lacunar type. The mental capacities of such patients may then appear to fail in a gradual and continuous fashion. Memory is relatively spared in the early stages and, usually, a pseudobulbar state or severe deterioration in gait accompany the dementia. The subcortical white matter change of Binswanger disease causes similar diagnostic problems, as discussed on pages 373 and 707. Beyond these vascular diseases and the familial disease Cadasil (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy, page 707), which is of uncertain cause, the authors have doubts about the entire category of vascular dementia and certainly of the frequency with which it is assumed to occur. Most cases turn out to be Alzheimer disease with one or more visible infarctions.

We are inclined toward the point of view expressed in Chap. 21 and summarized in the commentary by Jagust, specifically that while there may be an undefined but perhaps synergistic interaction between strokes and progressive mental decline in patients with Alzheimer disease, the relationship is unproven. Most often it is the degenerative condition of Alzheimer that explains the dementia.

**Dementia Due to Metabolic Diseases** (See Chap. 37) In the diagnosis of this large category of chronic dementias, one must consider several nondegenerative disorders in which dementia may predominate and focal neurologic abnormalities may be minimal. Several of the treatable ones were listed earlier in the discussion of Alzheimer disease above, and a larger group is reviewed in Chap. 21 and Table 21-3. Also to be considered, particularly among dementias with onset at an early age, are the inherited metabolic diseases discussed in Chap. 37, chief among which are the leukodystrophies—metachromatic, adrenal, globoid body (Krabbe disease)—and the poliodystrophies—neuronal ceroid lipofuscinosi.
DISEASES IN WHICH DEMENTIA IS A PROMINENT FEATURE WITH OTHER NEUROLOGIC ABNORMALITIES

Huntington Chorea

This disease—distinguished by the triad of dominant inheritance, choreoathetosis, and dementia—commemorates the name of George Huntington, a medical practitioner of Pomeroy, Ohio. In 1872, in a paper read before the Meigs and Mason Academy of Medicine and published later that year in the Medical and Surgical Reporter of Philadelphia, Huntington gave a succinct and graphic account of the disease, based on observations of patients that his father and grandfather had made in the course of their practice in East Hampton, Long Island. Reports of this disease had appeared previously (see DeJong, in the References, for historical background), but they lacked the accuracy and completeness of Huntington’s description. Vessie, in 1932, was able to show that practically all the patients with this disease in the eastern United States could be traced to about six individuals who had emigrated in 1630 from the tiny East Anglian village of Bures, in Suffolk, England. One remarkable family was traced for 300 years through 12 generations, in each of which the disease had expressed itself.

To quote Huntington, the rule has been that “When either or both of the parents have shown manifestations of the disease . . . one or more of the offspring invariably suffer of the disease, if they live to adult life. But if by any chance these children go through life without it, the thread is broken and the grandchildren and great-grandchildren of the original shakers may rest assured that they are free from disease.” Davenport, in a review of 962 patients with Huntington chorea, found only 5 who had descended from unaffected parents. Possibly, in these latter patients, a parent had the trait, but in very mild form. Or, one or more of these patients may have represented a rare sporadic instance of Huntington chorea, i.e., may have been an individual in whom a spontaneous mutation had occurred.

In university hospital centers, this is one of the most frequently observed types of hereditary nervous system disease. Its overall frequency is estimated at 4 to 5 per million, and 30 to 70 per million among whites of northern European ancestry. The usual age of onset is in the fourth and fifth decades, but 3 to 5 percent begin before the 15th year and some even in childhood. In about 30 percent, symptoms become apparent after 50 years. The progressions of the disease is slower in older patients. Once begun, the disease progresses relentlessly, until only a restricted existence in a nursing home or psychiatric hospital is possible and some other disease terminates life.

Exhaustive genealogic documentation has established the cause to be an autosomal dominant gene with complete penetrance (see below). Martin has made the observation that young patients usually inherit the disease from their fathers and older patients from their mothers. It has been observed beginning at almost the same age in identical twins.

Until recently, it had not been possible to foretell which of the children of a patient will be stricken with the disease. The most important achievement in respect to the presymptomatic detection and biologic understanding of Huntington disease was the discovery by Gusella and colleagues of a marker linked to the Huntington gene, localized to the short arm of chromosome 4. Subsequently these investigators and others identified the gene abnormality as an excessively long repeat of trinucleotides (CAG) within the Huntington gene, the length (number) of which determines not only the presence of the disease but also the age of onset, longer repeat lengths being associated with an earlier appearance of clinical signs. This discovery has made possible the development of a test for the detection of the defective gene in asymptomatic individuals. Since there is no treatment for the disease, testing raises certain ethical considerations that must be resolved before its widespread utilization.

Clinical Features The mental disorder assumes several subtle forms long before the more obvious deterioration of cognitive functions becomes evident. In approximately half the cases, slight and often annoying alterations of character are the first to appear. Patients begin to find fault with everything, to complain constantly, and to nag other members of the family; they may be suspicious, irritable, impulsive, eccentric, untidy, or excessively religious, or they may exhibit a false sense of superiority. Poor self-control may be reflected in outbursts of temper, fits of despondency, alcoholism, or sexual promiscuity. Disturbances of mood, particularly depression, are common (almost half of the patients in some series) and may constitute the most prominent symptoms early in the disease. Invariably, sooner or later, the intellect begins to fail. The patient becomes less communicative and more socially withdrawn. These emotional disturbances and changes in personality may reach such proportions as to constitute a virtual psychosis (with persecutory delusions or hallucinations).

Diminished work performance, inability to manage household responsibilities, and disturbances of sleep may prompt medical consultation. There is difficulty in maintaining attention, in concentration, and in assimilating new material. Mental flexibility lessens. There is loss of fine manual skills (see further on). The performance parts of the Wechsler Adult Intelligence Scale show greater loss than the verbal parts. Memory is relatively spared. This gradual dilapidation of intellectual function has been characterized as a “subcortical dementia” (page 372), i.e., elements of aphasia, agnosia, and apraxia are observed only rarely and memory loss is not profound. Often the process is so slow, particularly in cases of late onset, that some degree of intellectual capacity seems to be retained for many years.

The abnormality of movement is at first slight and most evident in the hands and face; often the patient is merely considered to be fidgety, restless, or “nervous.” Slowness of movement of the fingers and hands, a reduced rate of finger tapping, and difficulty in performing a sequence of hand movements are early motor signs. Gradually these abnormalities become more pronounced until the entire musculature is implicated with chorea. The frequency of blinking is increased (the opposite of parkinsonism), and voluntary protrusion of the tongue is constantly interrupted by unwanted darting movements. In the advanced stage of the disease, the patient is seldom still for more than a few seconds. The choreic movements are slower than the brusque jerks and postural lapses of Sydenham chorea, and they involve many more muscles. They tend to recur in stereotyped patterns yet are not as stereotyped as tics. In more advanced cases, they acquire an athetoid or dystonic quality. Muscle tone is usually decreased until late in the illness, when there

(Kufs disease), GM1 gangliosidosis, and Wilson disease (see page 840). Each of these displays characteristic neurologic features that may present in the early stages with a decline in intellectual function and a general behavioral disorder.
may also be some degree of rigidity, tremor, and bradykinesia, elements suggestive of Parkinson disease (the Westphal or “rigid” variant, which is more common with a childhood onset). Tendon reflexes are exaggerated in one-third of patients, but only a few have Babinski signs. Voluntary movements are initiated and executed more slowly than normal, but there is no weakness and no ataxia, although speech, which becomes dysarthric and explosive due to incoordination between tongue and diaphragm, may convey the impression of a cerebellar disorder. There is poor control of the tongue and diaphragm. In late-onset cases there may be an almost constant rapid movement of the tongue and mouth, simulating the tardive dyskinesia that follows the use of neuroleptic drugs. Denny-Brown pointed out that when the Huntington patient is suspended, the upper limbs assume a flexed posture and the legs an extended one, a posture that he considered to be expressive of the striatal syndrome. The disorder of movement that characterizes Huntington chorea has been described more fully in Chap. 4. Oculomotor function is subtly affected in most patients (Leigh et al; Lasker et al). Particularly characteristic are impaired initiation and slowness of both pursuit and volitional saccadic movements and an inability to make a volitional saccade without movement of the head. Excessive distractibility may be noticed during attempted ocular fixation. The patient feels compelled to glance at extraneous stimuli even when specifically instructed to ignore them. Upward gaze is often impaired.

As Wilson stated, the relation of the choreic to the mental symptoms “abides by no general rule.” Most often the mental symptoms precede the chorea, but they may accompany or follow it, sometimes by many years. In our own material, with several exceptions of late onset with rigidity rather than chorea, once the movement disorder was fully established, there was nearly always some degree, perhaps slight, of cognitive abnormality. Exceptional cases have been reported in which the movement disorder existed for 10 to 30 years without mental changes in patients with the gene abnormality of Huntington disease (Britton et al). After 10 to 15 years, most patients deteriorate to a vegetative state, unable to stand or walk and eating little; in this late stage, a mild amyotrophy may appear. Noteworthy is the high suicide rate in huntingtonians, as pointed out by Huntington himself (see also Schoenfeld et al). There is a higher than normal incidence of head trauma; therefore chronic subdural hematoma is another common finding at autopsy.

The first signs of the disease may appear in childhood, before puberty (even under the age of 4), and several series of such early-onset cases have been described (Farrer and Conneally; van Dijk et al). Mental deterioration at this early age is more often accompanied by cerebellar ataxia, behavior problems, seizures, bradykinesia, rigidity, and dystonia than by chorea (Byers et al). However, this rigid form of the disease (Westphal variant, as it is known) also occurs occasionally in adults, as mentioned above. Functional decline is much faster in children than it is in adults (Young et al).

At the gene locus in Huntington disease there are normally 11 to 34 (median 19) consecutive repetitions of the CAG triplet, each of which codes for glutamine. Individuals with 35 to 39 triplets may eventually manifest the disease, but it tends to be late in onset and mild in degree or limited to the below-mentioned senile chorea, and those with more than 42 almost invariably acquire the signs of disease if they live long enough.

Earlier onset in successive generations (anticipation) is well described in the early writings on the subject and is now known to be attributable to increasing lengths of the CAG repeat sequence. The dementia is generally more severe in cases of early onset (15 to 40 years) than in those of later onset (55 to 60 years). In adult patients with early onset, the emotional disturbance tends to be more prominent initially and precedes the chorea and intellectual loss by years; with older age of onset, choreiform features are more often the initial components; in the middle years, dementia and chorea have their onset at nearly the same age. At the other extreme of age, the first features may become evident in the eighties, with orofacial or other dyskinesias that are mistakenly attributed to an exposure to neuroleptic drugs.

Pathology and Pathogenesis Gross atrophy of the head of the caudate nucleus and putamen bilaterally is the characteristic abnormality, usually accompanied by a moderate degree of gyral atrophy in the frontal and temporal regions. The caudatal atrophy alters the configuration of the frontal horns of the lateral ventricles in that the inferolateral borders do not show the usual bulge formed by the head of the caudate nucleus. In addition, the ventricles are diffusely enlarged (Fig. 39-4); in CT scans, the bicaudate-cranial ratio is increased in the majority of patients, and this finding corroborates the clinical diagnosis in the moderately advanced case.

The early articles of Alzheimer and Dunlap and the more recent one of Vonsattel and DiFiglia contain the most authoritative descriptions of the microscopic changes. The latter authors have graded the disease into early, moderately advanced, and far advanced stages. In five early but genetically verified cases, no striatal lesion was found, which suggests that the first clinical manifestations are based on a biochemical disorder without visible structural change, at least by light microscopy. This view is supported by the observation that Huntington patients studied with PET show a characteristic decrease in glucose metabolism in the caudate nuclei, which appears early in the disease and precedes the loss of tissue (Hayden et al). The striatal degeneration begins in the medial part of the caudate nucleus and spreads, tending to spare the nuclear accumbents. Of the six cell types in the striatum (a differentiation based on size, dendritic arborizations, spines, and axon trajectories), the smaller neurons are affected before the larger ones. Loss of dendrites of the small spiny neurons has been an early finding, while the large cells are relatively preserved and exhibit no special alterations. The lost cells are replaced by fibrous astrocytes. The anterior parts of the putamen and caudate are more affected than the posterior parts. In our own cases we have not been impressed with changes in the globus pallidus, subthalamic nucleus, red nucleus, or cerebellum, but others have observed slight changes in these parts and in the pars reticulata of the substantia nigra. In the cerebral cortex, there is said to be slight neuronal loss in layers 3, 5, and 6, with replacement gliosis. Cases are reported with typical striatal lesions but normal cortices, in which only chorea had been present during late life. In our early to moderately advanced cases, even quantitative analyses of the cortex have not disclosed a significant loss of neurons. Several neuropathologists have observed marked cell loss and gliosis in the subthalamic nuclei in children or young adults with chorea and behavior disorders.

The biochemical defects in Huntington chorea are only beginning to be understood. Impaired glucose metabolism in the caudate nucleus, preceding visible atrophy, has already been noted in some studies. Since at least a partial explanation for L-dopa–induced involuntary movements is an excess of dopamine (in contrast to Parkinson disease, in which there is a decrease in dopamine), it has been postulated that the abnormal movements of Huntington chorea represent a heightened sensitivity of striatal dopamine receptors. There are disturbances in the metabolism of other putative
neurotransmitters (norepinephrine, glutamic acid decarboxylase, choline acetyltransferase, GABA, acetylcholine, and somatostatin), but the significance of these biochemical disturbances is unknown.

Viewed from the molecular perspective, the pathogenesis of this disease is a direct but still poorly understood consequence of the aforementioned expansion of the polyglutamine region of huntingtin (the protein product of the Huntington gene). It has been shown that the expansion predisposes the mutant huntingtin protein to aggregate in the nuclei of neurons. Moreover, the protein accumulates preferentially in cells of the striatum and parts of the cortex affected in Huntington disease. Evidence, particularly that given by Wetz (cited in the review by Bates), suggests that these aggregates may be toxic to neurons, either directly or in their protofibrillar form (a situation similar to that suggested for the toxicity of synuclein in Parkinson disease). The situation is, however, likely to be more complex, since the bulk of huntingtin deposition is found in cortical neurons, whereas the neuronal loss is predominantly striatal. One theory, based on experimental data, supports the concept that the polyglutamine expansion renders certain cell types unduly sensitive to glutamate-mediated excitotoxicity; another notion is that it creates an insufficiency of trophic influences directed to the caudate from the cortex; yet another theory relates the polyglutamine expansion to the acetylation of histones, which leads to cell death. This finding has led to trials of inhibitors of histone deacetylases and other therapies that modify gene expression in transgenic mouse models of Huntington disease. Other theories implicate mitochondrial dysfunction. As importantly, since polyglutamine expansions are implicated in several neurodegenerative diseases (reviewed below), treatments that block their effect on cellular function may be broadly effective in several degenerative diseases.

**Diagnostic Problems** Once the disease has been observed in its fully developed form, its recognition requires no great clinical acumen. The main difficulty arises with patients who lack a family history but who display the progressive chorea, emotional disturbance, and dementia with onset in adult life. This difficulty has been largely overcome since the mutation causing Huntington disease was identified. It is now possible to confirm or exclude the diagnosis by analysis of DNA from a blood sample. The presence of greater than 39 to 42 CAG repeats at the Huntington locus essentially confirms its presence; lesser numbers leave room for equivocation. Sometimes it is learned later that the family history was incomplete or falsified or that an illness in a parent had been misinterpreted.

Chorea that begins in late life, with only mild or questionable intellectual impairment and without a family history of similar disease, is another source of difficulty; referring to it as “senile chorea” does not solve the problem. Indeed, senile chorea may have more than one cause. We have seen it appear with infections, drug therapy, and thyrotoxicosis, only to disappear after a few weeks. A few times we have been confronted with the problem of an older patient who displays orolingual dyskinesias that are most characteristic of exposure to neuroleptic drugs but in whom there was no such history of exposures; testing disclosed Huntington disease.

Chorea in early adult life always raises the question of a late form of Sydenham chorea, of lupus erythematosus with antiphospholipid antibodies, or of cocaine use, but neither familial occurrence nor mental deterioration is part of these processes. A “benign inherited chorea,” transmitted as an autosomal dominant trait without prolongation of a triplet sequence, has been traced to chromosome 14q. It is differentiated from Huntington disease by onset before age 5, progressing little and having no associated mental deterioration (Breedveld et al). Other progressive neurologic disorders inherited as autosomal dominant traits and beginning in adolescence or adult life (e.g., polymyoclonus with or without ataxia, acanthocytosis with progressive chorea, and dentatorubropallidolysian degeneration) can closely mimic Huntington disease, as described further on; sometimes only the genetic and pathologic findings settle the matter.

There are several other rare degenerative disorders with chorea, some of which have already been mentioned. A midlife progressive chorea without dementia (after more than 25 years follow-
up) that does not display the Huntington genotype has been reported. In at least one family in which this clinical picture is dominantly inherited, the fundamental defect is a mutation in the gene encoding the light chain (L chain) of ferritin (Curtis). Affected individuals have axonal changes in the pallidum with swollen, ubiquitin- and tau-positive aggregates; serum ferritin levels may be depressed. The implication of this mutation is that perturbations of iron metabolism may be toxic to neurons, a feature that also characterizes Hallervorden-Spatz disease (page 832).

**Dentatorubropallidoluysian atrophy** (DRPLA), often misdiagnosed clinically as Huntington chorea, was described in four European families by Warner and associates and is discussed further on in the section on cerebellar degenerations. The extrapyramidal manifestations include chorea, myoclonus, and rigidity. Adult-onset chorea and dementia has been described with *propionic academia*; propionic acid is elevated in the plasma, urine, and CSF. This disorder must be added to other metabolic diseases described in Chap. 37 as causes of chorea and dyskinesia—such as glutaric acidemia, keratin sulfaturation, calcification of basal ganglia, phenylketonuria, and Hallervorden-Spatz disease (Hagberg et al).

Other problems in differential diagnosis include bilateral thalamic degeneration with dementia and chorea, referred to earlier; paroxysmal choreoathetosis (page 68); Wilson disease (page 830); acquired hepatocerebral degeneration (page 975); and, most often and especially, tardive dyskinesia (page 94). Many drugs in addition to the toxic effects of L-dopa and antipsychotic medications occasionally cause chorea (amphetamines, cocaine, tricyclic antidepressants, lithium, sibutramine). Haloperidol may also help alleviate abnormalities of behavior or emotional lability, but it does not alter the progress of the disease. The authors have not been impressed with the therapeutic effectiveness of other currently available drugs. Levodopa and other dopamine agonists make the chorea worse and, in the rigid form of the disease, evoke chorea. Drugs that deplete dopamine or block dopamine receptors—such as reserpine, clozapine, and tetrabenazine—suppress the chorea to some degree, but their side effects (drowsiness, akathisia, and tardive dyskinesia) outweigh their desired effects. The juvenile (rigid) form of the disease is probably best treated with antiparkinsonian drugs. Preliminary studies of the transplantation of fetal ganglionic tissue into the striatum achieved mixed results. The psychologic and social consequences of the disease require supportive therapy, and genetic counseling is essential. Huntington disease pursues a steadily progressive course and death occurs as mentioned, on average 15 to 20 years after onset, sometimes much earlier or later.

**Treatment** The dopamine antagonist haloperidol, in daily doses of 2 to 10 mg, is probably the most effective agent in suppressing the movement disorder. Because of the danger of superimposing tardive dyskinesia on the chronic disorder, the chorea should be treated only if it is functionally disabling, using the smallest possible dosages. Haloperidol may also help alleviate abnormalities of behavior or emotional lability, but it does not alter the progress of the disease. The authors have not been impressed with the therapeautic effectiveness of other currently available drugs. Levodopa and other dopamine agonists make the chorea worse and, in the rigid form of the disease, evoke chorea. Drugs that deplete dopamine or block dopamine receptors—such as reserpine, clozapine, and tetrabenazine—suppress the chorea to some degree, but their side effects (drowsiness, akathisia, and tardive dyskinesia) outweigh their desired effects. The juvenile (rigid) form of the disease is probably best treated with antiparkinsonian drugs. Preliminary studies of the transplantation of fetal ganglionic tissue into the striatum achieved mixed results. The psychologic and social consequences of the disease require supportive therapy, and genetic counseling is essential. Huntington disease pursues a steadily progressive course and death occurs as mentioned, on average 15 to 20 years after onset, sometimes much earlier or later.

**Acanthocytosis with Chorea**

A few reports of a slowly progressive, familial chorea and dementia in association with an abnormality of erythrocytes have appeared in English, American, and Japanese journals. The disease has the following characteristics: (1) onset in adolescence or early adult life of generalized involuntary movements (described as chorea but including dystonia and tics), usually beginning as an orofacial dyskinesia and spreading to other parts of the body and to other neural systems; (2) mild to moderate mental deterioration with behavioral disturbance in some but not all cases; (3) decreased or absent tendon reflexes and evidence of chronic axonal neuropathy and degeneration atrophy of muscles; (4) atrophy and gliosis of the caudate nuclei and putamens but no neuronal loss in the cerebral cortex or other parts of the brain; (5) the defining element, acanthocytosis (thorny and spiky appearance of erythrocytes); and (6) an autosomal recessive inheritance pattern. The acanthocytosis, according to Sasaki and coworkers, is due to an abnormal composition of covalently (tightly) bound fatty acids in erythrocyte membrane proteins (palmitic and docosahexaenoic acids increased and stearic acid decreased). Although the inheritance is usually autosomal recessive, at least one family with the dominantly transmitted trait has been described. The acanthocytosis may be overlooked when it is mild but can be detected by scanning electron microscopy. In the series of 19 cases reported by Hardie and colleagues, the manifestations included dystonia, tics, vocalizations, rigidity, and lip and tongue biting; more than half had cognitive impairment or psychiatric features. The average age of onset was 32 years; 7 of the 19 cases were sporadic. The disease has been linked in almost all families to chromosome 9q, where there is a mutation in the gene encoding a large (3100–amino acid) protein designated chorein that is thought to be involved in cellular protein sorting and trafficking (Rampoldi). Some of the families with dominantly inherited neuroacanthocytosis have mutations in the chorein gene.

McLeod’s disease, another choreiform disorder with acanthocytosis and the gradual development of chorea in middle to late life, is characterized by degeneration of the caudate and putamen and a myopathy (elevated serum CPK). These individuals have fewer facial tics and orofacial features than those with neuroacanthocytosis. McLeod’s syndrome arises from mutations in a gene on the X chromosome that encodes the KX protein, which binds to surface Kell antigens on red cells. In addition to the primary KX gene mutations, these individuals show diminished Kell antigen expression on the red-cell surface.

**Corticostriatospinal Degenerations**

Included in this category are a somewhat heterogeneous group of degenerative diseases in which the symptoms of parkinsonism and corticospinal degeneration present in various combinations. Some of the diseases that make up this group have not been sharply delineated and are difficult to separate from one another (see also page 928).

Variants of this category of disease continue to appear. The authors have observed several patients in whom extreme rigidity, corticospinal signs, but no dementia have developed over a period of several years. In the later stages of the disease, the patient, while alert, is totally helpless—unable to speak, swallow, or move the limbs. Only eye movements are retained, and even these are hampered by supranuclear gaze palsies in advanced cases. Intellectual functioning appears to be better preserved than movement but is difficult to assess. Other bodily functions are intact. The course is slowly progressive and ends fatally in 5 to 10 years. There is no family history of similar disease, and there are no clues as to causation. Gilbert and colleagues have described similar cases with signs of Parkinson disease, motor neuron disease, and dementia; in their cases, there were no senile plaques or Lewy bodies. The concurrence of typical motor neuron disease and Parkinson disease may be coincidental, but Qureshi and colleagues described 13 patients in whom both clinical phenomena began within a short time.
and they considered them to be related. In the variant described by Tandan and colleagues, an autosomal dominant syndrome of Charcot-Marie-Tooth polyneuropathy was combined with ptosis, parkinsonism, and dementia, again without Lewy bodies or senile plaques. Other variants have been described by Schmitt and co-workers and by Mata and colleagues. Hudson has reviewed 42 sporadic cases in which ALS-parkinsonism-dementia were combined (see References).

Under the title “Spastic Pseudosclerosis,” Jakob, in 1921, described a chronic disease of middle to late adult life, characterized by abnormalities of behavior and intellect; weakness, ataxia, and spasticity of the limbs (chiefly the legs); extrapyramidal symptoms such as rigidity, slowness of movement, tremors, athetotic postures, and hesitant, dysarthric speech; and normal spinal fluid. The pathologic changes were diffuse and consisted mainly of an outfall of neurons in the frontal, temporal, and central motor gyri, corpus striatum, ventromedial thalamus, and bulbar motor nuclei. In one of Jakob’s cases, there were also prominent changes in the anterior horn cells and corticospinal tracts in the spinal cord like those of ALS. The latter finding gave rise to Wilson’s concept of the disease as a corticostriatospinal degeneration. A degenerative and probably familial disorder that had been described earlier by Creutzfeldt was considered by Spielmeyer to be sufficiently similar to the one of Jakob to warrant the designation Creutzfeldt-Jakob disease.

As discussed in Chap. 33, the disorder described by Creutzfeldt and Jakob has been a source of endless controversy because of its indeterminate character. On the one hand, it has been confused with the subacutely evolving myoclonic dementia, or subacute spongiform encephalopathy, which is now known to be an infection due to an unconventional transmissible prion agent. The authors believe that the latter disease, which is described on page 653, bears at best only a superficial resemblance to the one described by Creutzfeldt and Jakob and that the two disorders should be clearly separated. Unfortunately, the use of the eponym for the prion-related disease is so entrenched in medical usage that any attempt to delete it stands little chance of success. On the other hand, sporadic and familial cases that are not transmissible and lack a prominent spongiform change merge with a rather heterogeneous but overlapping group of degenerative disorders, all rare, including progressive dementia and spastic paraplegia, progressive frontotemporal dementia and ALS, the Parkinson-dementia-ALS complex of Guam, and the corticopallidalspinal degeneration of Davison.

One is tempted to conclude that the spastic pseudosclerosis of Jakob may not constitute a disease type, and certainly everyone agrees that the term pseudosclerosis (also used for the Westphal-Strümpell form of hepatolenticular degeneration) is meaningless.

The Guamanian Parkinson-dementia-ALS complex deserves separate comment because it has been well defined in a large number of carefully studied cases with almost uniform clinical and pathologic features. The disease occurs in the indigenous Chamorro peoples of Guam and the Marianas islands, predominantly in men between ages 50 and 60. Progressive parkinsonism and dementia are combined with upper or lower motor neuron disease (ALS is also common among the Chamorros), leading to death in 5 years. The pathologic changes, described by Hirano and others, consist of severe cortical atrophy with neurofibrillary tangles but, notably, no detectable amyloid plaques, even with sensitive neurochemical staining. As in Parkinson disease, the substantia nigra and to a lesser extent other pigmented nuclei are depopulated of nerve cells but contain no Lewy bodies. Cases with amyotrophy show the typical loss of anterior horn cells. The cause of the Guamanian multisystem degeneration is not known, although several studies have incriminated one or more adverse environmental influences, including putative neurotoxins in the food supply.

**Familial Dementia with Spastic Paraparesis**

From time to time the authors have encountered families in which several members developed a spastic paraparesis and a gradual failure of intellectual function during the middle adult years. The patient’s mental horizon narrowed gradually, and the capacity for high-level thinking diminished; in addition, the examination showed appropriately exaggerated tendon reflexes, clonus, and Babinski signs. In one such family the illness had occurred in two generations; in another, three brothers in a single generation were afflicted. Skre described two recessive types of hereditary spastic paraplegia in Norway, one with onset in childhood, the other in adult life. In contrast to the dominant form (see further on), the recessive types displayed evidence of more widespread involvement of the nervous system, including dementia, cerebellar ataxia, and epilepsy. Also, Cross and McKusick have observed a recessive type of paraplegia accompanied by dementia beginning in adolescence. They named it the Mest syndrome, after the afflicted family.

Worster-Drought and others have reported the pathologic findings in two cases of this type. In addition to senile plaques and neurofibrillary changes, there was demyelination of the subcortical white matter and corpus callosum and a “patchy but gross swelling of the arterioles,” which gave the staining reactions for amyloid (“Scholz’s perivascular plaques”). Van Bogaert and associates published an account of similar cases that showed the characteristic pathologic features of Alzheimer disease.

Adult forms of metachromatic leukodystrophy and adrenoleukodystrophy may present with a similar clinical picture (Chap. 37). Quite rare instances of the same syndrome with adult onset have turned out to be due to phenylketonuria or other aminoacidopathies (see Chap. 37). Another interesting association of familial spastic paraplegia is with progressive cerebellar ataxia. Fully one-third of the cases that we have seen with such a spastic weakness were also ataxic and would fall into the category of spinocerebellar degenerations. Yet another variant of this group of diseases has been described by Farmer and colleagues; the inheritance in their cases was autosomal dominant, and the main clinical features were deafness and dizziness, ataxia, chorea, seizures, and dementia, evolving in that order. Postmortem examinations of two patients disclosed calcification in the globus pallidus, neuronal loss in the dentate nuclei, and destruction of myelinated fibers in the centrum semiovale.

**Adult Polyglucosan Body Disease**

Under this title, Robitaille and colleagues have described a distinct type of progressive neurologic disease in adults characterized clinically by spasticity, chorea, dementia, and a predominantly sensory polynuropathy. Structures that closely resembled Lafora bodies and corpora amylaceae were found in large numbers in both central and peripheral neural processes (mainly in axons) and also in astrocytes. These basophilic PAS-positive structures (up to 40 μm in size) were composed of glucose polymers (polyglucosans) and were readily demonstrated in sural nerve biopsies. Some were also found in the heart and liver.
More recently, Rifal and associates have reviewed the findings in 25 cases of this disease— one observed personally and 24 reported previously. The dementia appears to be relatively mild, consisting of impairment of retentive memory, dysnomia, dyscalculia, and sometimes expressive dysphasia and deficits of "visual integration"; this was overshadowed by the rigidity and spasticity of the limbs and the peripheral nerve disorder. Nerve conduction velocities were diminished and the leg muscles were denervated. Moderate degrees of generalized cerebral atrophy, multifocal areas of white matter rarefaction, and increased iron deposition in the putamina was disclosed by MRI. The finding of polyglycosan axon inclusion in biopsied nerve confirms the diagnosis. The disease has sometimes been misdiagnosed as adrenoleukodystrophy. Its status is unclear to the authors, and there is no treatment.

**DISEASES CHARACTERIZED BY ABNORMALITIES OF POSTURE AND MOVEMENT**

**Parkinson Disease (Paralysis Agitans)**

This common disease, known since ancient times, was first cogently described by James Parkinson in 1817. In his words, it is characterized by "involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forward, and to pass from a walking to a running pace, the senses and intellect being uninjured." Strangely, his essay contains no reference to rigidity or to slowness of movement, and it stresses unduly the reduction in muscular power. The same criticism can be leveled against the term *paralysis agitans*, which appeared for the first time in 1841 in Marshall Hall’s textbook *Diseases and Derangements of the Nervous System*.

The natural history of the disease is of interest. As a rule, it begins between 40 and 70 years of age, with the peak age of onset in the sixth decade. It is infrequent before 30 years of age, and most series contain a somewhat larger proportion of men. Trauma, emotional upset, overwork, exposure to cold, "rigid personality," and so on, are among many factors that have been suggested over the years as predisposing to the disease, but there is no convincing evidence to support any such claims. A possible relationship to repeated cerebral trauma and to the "punch-drunk" syndrome (dementia pugilistica, page 863) has been particularly problematic and is unresolved despite several celebrated cases (Lees). Idiopathic Parkinson disease is observed in all countries, all ethnic groups, and all socioeconomic classes, although the incidence in African Americans is only one-quarter that in whites. In Asians, the incidence is one-third to one-half that in whites. The disease is frequent in North America, where there are approximately 1 million patients, constituting about 1 percent of the population over the age of 65 years. The incidence in all European countries where vital statistics are kept is similar.

**Genetic Aspects** Considering its frequency, coincidence in a family on the basis of chance occurrence might be as high as 5 percent. A lack of concordance of Parkinson disease in twins was at first thought to negate the role of genetic factors, but a study of dopamine metabolism utilizing PET scanning has shown that 75 percent of asymptomatic twins of Parkinson patients had evidence of striatal dysfunction and only a small portion of dizygotic twins showed these changes (Piccini et al). These data suggest a more substantial role for an inherited trait in cases of ostensibly sporadic disease (see below regarding the Parkin mutations). Also, Krüger and colleagues have reported a 13-fold increased susceptibility to the disease in patients who harbor a combination of certain α-synuclein and apolipoprotein E genotypes, but this awaits confirmation.

While familial cases are decidedly rare (Table 39-2), Golbe and colleagues advanced the understanding of the genetic underpinning of the disease by describing two large kindreds (probably related and originating from a small town in southern Italy) in which 41 patients in four generations were affected. The illness in their cases was characteristic of Parkinson disease both clinically and pathologically, the only unusual features being a somewhat earlier onset (mean age 46 years), a relatively rapid course (10 years from onset to death), and a low incidence of tremor (only 8 of the 41 patients). The dominantly inherited parkinsonism described by Dwor and others also differed clinically (onset in the third decade, prominence of dystonia) and pathologically (absence of Lewy bodies) from classic Parkinson disease. It was in the latter kindred and in three Greek families that Polymeropoulos et al identified a locus on chromosome 4q that contained a mutation in the gene encoding the protein α-synuclein, a main component of the Lewy body. Other families in which there have been mendelian patterns of inheritance have gene defects at other sites. These genetic data have been reviewed by Dunnett and Björklund. It is now clear that while such mutations are uncommon in the usual late-onset sporadic form of Parkinson disease, they are predominant in earlier-onset cases (see below). The main mutations are summarized in Table 39-2.

More recently, there has been emphasis on mutations on 1 of 12 exons in the so-called Park2 gene, which codes for the protein parkin on chromosome 6q (see Table 39-2). The commonest types are point mutations or deletions in exon 7, but abnormalities of the other exons evince similar syndromes. Homozygous mutations generally give rise to early-onset disease, but certain hemizygous changes (in exon 7) are also associated with a later onset. The resultant syndromes have been termed parkin disease to distinguish them from the idiopathic variety. It has been estimated by Kahn and colleagues that 50 percent of families that display an early onset of Parkinson disease and 18 percent of sporadic cases with early onset (before age 40) harbor mutations in this gene. Perhaps of greater clinical interest is finding that up to 2 percent of late-onset cases are due to parkin mutations. Sequencing of this gene is now available in commercial laboratories for the purposes of detecting mutations.

From a clinical perspective, the presentation of the late-onset cases with parkin mutations has been quite variable. Collectively they can often be identified by two outstanding features: an extreme sensitivity to L-dopa, maintaining an almost complete suppression of symptoms over decades with only small doses of medication; also, they have a low threshold for dyskinesias. We can corroborate from experience with our own patients an excellent response of tremor, postural changes, and bradykinesia to anticholinergic drugs. Moreover, most of these patients may enjoy a remarkable restorative benefit from sleep, which creates an apparent diurnal pattern of symptoms. Several series, particularly the ones of Lohmann and of Kahn and colleagues, indicate that there may be a wide variety of additional features: hyperreflexia (which we can also attest to); cervical, foot, or other focal dystonias, sometimes induced only by exercise; and, less often, autonomic dysfunction, peripheral neuropathy, and psychiatric symptoms. The sensitivity to medication and sleep benefit have long been known as the distinguishing components of juvenile-onset parkinsonism, which proves also to be derived from a different parkin mutation.
Clinical Features  A tetrad of hypo- and bradykinesia, resting tremor, postural instability, and rigidity are the core features of Parkinson disease. These are evident as expressionless face, poverty and slowness of voluntary movement, “resting” tremor, stooped posture, axial instability, rigidity, and festinating gait. These manifestations of basal ganglionic disease have been fully described in Chap. 4, and only certain diagnostic problems and nuances of the clinical picture need be considered here. The early symptoms may be difficult to appreciate and are often overlooked by family members because they evolve slowly and tend to be attributed to the natural changes of aging. The voice becomes soft and monotonous. For a long time the patient may not be conscious of the inroads of the disease. At first the only complaints may be of aching of the back, neck, shoulders, or hips and of vague weakness. A slight stiffness and slowness of movement or a reduction in the natural swing of one arm during walking are ignored, until one day it occurs to the physician or to a member of the family that the patient has the cast of Parkinson disease. Infrequency of blinking, as pointed out originally by Pierre Marie, is often a helpful early sign. The usual blink rate (12 to 20 per minute) is reduced in the parkinsonian patient to 5 to 10 per minute, and with it there is a slight widening of the palpebral fissures, creating a stare (Stellwag sign). A reduction in movements of the small facial muscles imparts the characteristic expressionless “masked” appearance (hypomimia). When seated, the patient makes fewer small shifts and adjustments of position than the normal person (hypokinesia), and the fingers straighten and assume a flexed and adducted posture at the metacarpophalangeal joints.

The characteristic tremor, which usually involves a hand, is often listed as the initial sign; but in at least half the cases, observant family members will already have remarked on the patient’s relative immobility and reduction or slowness of movement. Moreover, in 20 to 25 percent of cases the tremor is mild and intermittent or evident in only one finger or one hand. The tremor of the fully developed case takes several forms, as was remarked in Chap. 6. The four-per-second “pill-rolling” tremor of the thumb and fingers, while most characteristic, is seen in only a proportion of patients and is typically present when the hand is motionless, i.e., not used in voluntary movement (hence the term resting tremor). Complete relaxation, however, greatly reduces or abolishes the tremor, and a volitional movement usually dampens it momentarily. The rhythmic beat coincides with an alternating burst of activity in agonist and antagonist muscles in the electromyogram (EMG); hence the apt description alternating tremor is also applied. The arm, jaw, tongue, eyelids, and foot are less often involved. Even the least degree of tremor is felt during passive movement of a rigid part (cogwheel phenomenon, or Negro’s sign). The tremor shows surprising fluctuations in severity and is aggravated by walking and excitement, but the frequency of the tremor remains constant (Hunker and Abbs). It bears repetition that one side of the body is typically involved before the other, and the classic tremor then remains asymmetrical as the illness advances.

Lance and associates have called attention to a second common type of tremor in Parkinson disease—a fine, seven- to eight-per-second, slightly irregular action tremor of the outstretched fingers and hands. This tremor, unlike the slower one, persists throughout voluntary movement, is not evident with the limb in a resting position, and is more easily suppressed by relaxation. Electromyographically, it lacks the alternating bursts of action potentials seen in the more typical tremor and resembles, if not equates with, essential tremor (page 81, Table 6-1). It is subject to different medications than those used for the alternating tremor. The Parkinson patient may have either type of tremor or both.

We have been less impressed with rigidity and hypertonus as...
Obstacles such as door thresholds have the opposite effect, at times by sensory guidance, as by holding the patient at the elbow. Given the degree of postural instability, gait is typically improved by sensory guidance, as by holding the patient at the elbow. Obstacles such as door thresholds have the opposite effect, at times causing the patient to “freeze” in place. Getting in and out of a car or elevator or walking into a room or in a hall are then particularly difficult. Difficulty in turning over in bed is a characteristic feature as the illness advances, but the patient rarely volunteers this information; several of our patients have fallen out of bed at a frequency that suggests a connection to their reduced mobility. Shaving or applying lipstick becomes difficult, as the facial muscles become more immobile and rigid.

Persistent extension or clawing of the toes, jaw clenching, and other fragments of dystonia, often painful, may enter the picture but are not usually early findings. (These are particularly resistant to treatment.)

As noted above, these various motor impediments and tremors characteristically begin in one limb (more often the left) and spread to one side and later to both sides, until the patient is quite helpless. Yet in the excitement of some unusual circumstance (as escaping from a fire, for example), the patient with all but the most advanced disease is capable of brief but remarkably effective movement (kinesis paradoxica).

Regarding other elicitable neurologic signs, there is an inability to inhibit blinking in response to a tap over the bridge of the nose or glabella (Myerson sign), but grasp and suck reflexes are not present and buccal and jaw jerks are rarely enhanced. Commonly there is an impairment of upward gaze and convergence; if prominent or noted early in the disease, this sign suggests more the possibility of progressive supranuclear palsy. The bradykinesia may extend to eye movements, in that there is a delay in the initiation of gaze to one side, slowing of conjugate movements (decreased maximal saccadic velocity), hypometric saccades, and breakdown of pursuit movements into small saccades. There are no sensory changes, but a variety of paresthetic complaints are common. Drooling is troublesome; an excess flow of saliva has been assumed, but actually the problem is one of failure to swallow with normal frequency. Seborrhea and excessive sweating are probably secondary as well, the former due to failure to cleanse the face sufficiently, the latter to the effects of the constant motor activity.

Postural instability can be elicited by tugging at the patient’s shoulders from behind and noting the lack of a small step backward to maintain balance. The tendon reflexes vary, as they do in normal individuals, from being barely elicitable to brisk. Even when Parkinsonian symptoms are confined to one side of the body, the reflexes are usually equal on the two sides, and the plantar responses are flexor. Exceptionally, the reflexes on the affected side are slightly brisker, which raises the question of corticospinal involvement; but the plantar reflex remains flexor. In these respects, the clinical picture differs from that of corticobasal ganglionic degeneration, in which rigidity, hyperactive tendon reflexes, and Babinski signs are combined with apraxia (see further on). There is a tendency to orthostatic hypotension and sometimes syncope; this has been attributed by Rajput and Rozdilsky to cell loss in the substantia nigra. The description of the syncope is unfortunately confusing; the typical situation involves inability to stand up from a sitting position or an occasional syncopal episode when the patient is sitting and leaning forward. The patient may have a sudden onset of weakness, slurred speech, visual disturbances, dizziness, pallor, and sweating; there may be a brief episode of bradycardia; and the patient often feels cold and clammy, with paresthesias and occasional numbness. The patient often feels “pulling” or “stretching” sensations in the upper extremities, often the face.

As the disorder of movement worsens, all customary activities show the effects. Handwriting becomes small (micrographia), tremulous, and cramped, as first noted by Charcot. The voice softens and the speech seems hurried and monotonous and mumbling; the voice becomes less audible and finally the patient only whispers. Cackebeke and coworkers refer to the speech disorder as a “hypokinetic dystarhria”; they attribute it to respiratory, phonatory, and articulatory dysfunction. There is a failure to fully close the mouth. The consumption of a meal takes an inordinately long time. Each morsel of food must be swallowed before the next bite is taken.

Walking becomes reduced to a shuffle; the patient frequently loses balance, and in walking forward or backward may seem to be “chasing” the body’s center of gravity with a series of short steps in order to avoid falling (festination). Defense and righting reactions are faulty. Falls do occur, but surprisingly infrequently given the degree of postural instability. Gait is typically improved by sensory guidance, as by holding the patient at the elbow. Obstacles such as door thresholds have the opposite effect, at times
our experience. The incidence increases with advancing age, approaching 65 percent in Parkinson patients above 80 years of age, but it may be disabling even in patients in their late fifties. In some instances of Parkinson disease with dementia, MRI reveals lesions in the cerebral white matter (in T1-weighted images). They are not seen in parkinsonians without dementia. The pathologic basis of the dementia is discussed below.

The overall course of the disease is quite variable. In the majority of patients, the mean period of time from inception of the disease to a chairbound state is 7.5 years, but again, with a wide range (Hoehn and Yahr; Martilla and Rinne). On the other hand, as many as one-third of cases are relatively mild and such patients may remain stable for 10 years or more.

Much can still be gained from perusal of the study by Hoehn and Yahr, published in 1967, before the widespread use of L-dopa. Table 39-3 is reproduced from that paper.

### Diagnosis

Early in the course of Parkinson disease, when only a slight asymmetry of stride or an ineptitude of one hand is present and tremor has yet to appear and impart the unmistakable stamp of the disease, a number of small signs already mentioned may be helpful in diagnosis. These include a reduced blink rate, the Myerson glabellar sign, a lack of arm swing, digital impedance in a succession of movements (a tendency for rapid alternating movements to be slowed, to assume a tremor rhythm, or to be blocked altogether), and perceptible rigidity of one arm when the opposite limb is occupied in a motor task such as tracing circles in the air. Lack of a Babinski sign or of increased tendon reflexes in the affected limbs eliminates a corticospinal lesion as the cause of slowed movements, and lack of a grasp reflex helps to exclude a premotor cerebral disorder.

The two main difficulties in diagnosis are to distinguish typical Parkinson disease from the many parkinsonian syndromes caused by other degenerative diseases and by medications or toxins and to distinguish the Parkinson tremor from other types. It is worth noting that Parkinson disease is far more common than any of the syndromes that resemble it. Bradykinesia and rigidity of the limbs and axial musculature are symptoms shared with other forms of parkinsonism, but only in Parkinson disease does one see an early sign of “resting” alternating tremor that is more prominent in one arm.

The typical signs of Parkinson disease, when present in their entirety, impart an unmistakable clinical picture. When not all the signs are evident, there is no alternative but to re-examine the patient at several-month intervals until it is clear that Parkinson disease is present or until the signature of another degenerative process becomes evident (e.g., vertical gaze impairment in progressive supranuclear palsy; dysautonomia with fainting, blader, or vocal cord signs in striatoniagral degeneration; early and rapidly evolving dementia or psychosis in Lewy body disease, or apraxia in corticobasal ganglionic degeneration). If the patient’s symptoms warrant, a beneficial response to levodopa or a dopamine agonist also gives a reasonably secure although not entirely conclusive indication of the presence of Parkinson disease (see further on). The other parkinsonian syndromes are for the most part unchanged by the drug. Conversely, although some experts disagree, we have adhered to the notion that complete resistance of the symptoms to L-dopa early in the illness makes the diagnosis unlikely.

The epidemic of encephalitis lethargica (von Economo encephalitis) that spread over western Europe and the United States after the First World War left great numbers of parkinsonian cases in its wake. No definite instance of this form of encephalitis had been recorded before the period 1914–1918, and virtually none has been seen since 1930; hence postencephalitic parkinsonism is no longer a diagnostic consideration. Rarely, a Parkinson-like syndrome has been described following other forms of encephalitis, particularly with Japanese B virus, West Nile virus, and eastern equine encephalitis. In the few cases caused by these viruses that we have observed, there has been symmetrical rigidity, hypokinesia, and little or no tremor.

In England and Europe, an “arteriopathic” or “arteriosclerotic” form of Parkinson disease was at one time much diagnosed, but we have never been convinced of its reality. Pseudobulbar palsy from a series of lacunar infarcts or fromBinswanger disease (page 707) can cause a clinical picture that simulates certain aspects of Parkinson disease, but unilateral and bilateral corticospinal tract signs, hyperactive facial reflexes, spasmodic crying and laughing, and other characteristic features distinguish spastic bulbar palsy from Parkinson disease. Of course, the parkinsonian patient in advancing years is not impervious to cerebrovascular disease, and the two conditions then overlap.

Normal-pressure hydrocephalus can undoubtedly create a syndrome resembling Parkinson disease, particularly in regard to gait and postural instability and at times to bradykinesia; but rigid postures, slowness of alternating movements, hypokinetic ballistic movements, and resting tremor are not part of the clinical picture. Sometimes a lumbar puncture gives surprising benefit, then indicating hydrocephalus as the cause of the motor slowing.

Essential tremor is distinguished by its fine, quick quality, its tendency to become manifest during volitional movement and to disappear when the limb is in a position of repose, and the lack of associated slowness of movement, flexed postures, etc. The head and voice are more often involved in essential tremor than in Parkinson disease. Some of the slower, alternating forms of essential tremor are difficult to distinguish from parkinsonian tremor; one can only wait to see whether it is the first manifestation of Parkinson disease. An asymmetrical or unilateral tremor favors Parkinson disease. Also as noted, a faster oscillation is often mixed with the slow alternating Parkinson tremor, but the fast-frequency tremor is seldom an opening feature of the disease.

Progressive supranuclear palsy (see further on) is characterized by rigidity and dystonic postures of the neck and shoulders, a staring and immobile countenance, and a tendency to topple when walking—all of which are vaguely suggestive of Parkinson disease. Early falls are particularly suggestive of this disease, and are not typical of Parkinson disease until its late stages; there are, how-

ever, exceptions. Inability to produce vertical saccades and, later, paralysis of upward and downward gaze and eventually of lateral gaze with retention of reflex eye movements establish the diagnosis in most cases. Strict adherence to the diagnostic criteria for Parkinson disease also permits its differentiation from corticostriatospinal, striatonigral, and corticobasal ganglionic degeneration as well as Machado-Joseph disease—all of which are discussed in other parts of this chapter.

The rapid onset of parkinsonism should suggest exposure to neuroleptic medications or a variant of Creutzfeldt-Jakob disease.

Paucity of movement, unchanging attitudes and postural sets, and a slightly stiff and unbalanced gait may be observed in patients with an anergic or hypokinetid ("retarded") type of depression. Since as many as 25 to 30 percent of parkinsonian patients are depressed, the separation of these two conditions is at times difficult. The authors have seen patients who were called parkinsonian by competent neurologists but whose movements became normal when antidepressant medication or electroconvulsive therapy was given. Several such patients have nonetheless insisted that levodopa helps them in some nondescript way.

The rapid onset of the Parkinson syndrome, especially in conjunction with other medical diseases, should always raise the suspicion of drug effects; phenothiazines, haloperidol, and the neuroleptics pimozide and metoclopramide, used at times as antiemetics, all cause a slight masking of the face, stiffness of the trunk and limbs, lack of arm swing, fine tremor of the hands, and mumbling speech. They may also evoke an inner restlessness, a "muscular impatience," an inability to sit still, and a compulsion to move about much like that which occurs at times in the parkinsonian patient (akathisia; page 97). Spasms of the neck, face, and jaw muscles (open mouth, protruded tongue, retrocollis or torticollis, grimacing) may also be provoked by such drugs. Even the newer antipsychotic medications, favored specifically because of a putative lack of extrapyramidal effects, may be at fault. A mild, localized rigidity of an arm due to local tetanus was studied by R. D. Adams in a patient who had been referred as a case of acute parkinsonism.

All in all, if one adheres to the strict definition of Parkinson disease—bradykinesia, "resting" tremor, postural changes and instability, cogwheel rigidity, and response to L-dopa—errors in diagnosis are few. Yet in a series of 100 cases, studied clinically and pathologically by Hughes and associates, the diagnosis was inaccurate in 25 percent. The reasons are that about this number of Parkinson patients fail to display the characteristic tremor and about 10 percent are said to not respond to L-dopa. These authors noted that early dementia and autonomic disorder and the presence of ataxia and corticospinal signs were reliable guides to an alternate diagnosis.

Pathology and Pathogenesis The most constant and pertinent finding in both idiopathic and postencephalitic Parkinson disease is a loss of pigmented cells in the substantia nigra and other pigmented nuclei (locus ceruleus, dorsal motor nucleus of the vagus). The substantia nigra is visibly pale to the naked eye; microscopically, the pigmented nuclei show a marked depletion of cells and replacement gliosis, and some of the remaining cells have reduced quantities of melanin, findings that enable one to state with confidence that the patient must have suffered from Parkinson disease. Also, many of the remaining cells of the pigmented nuclei contain eosinophilic cytoplasmic inclusions, surrounded by a faint halo, called Lewy bodies (Fig. 39-5). These are seen in practically all cases of idiopathic Parkinson disease. They were generally absent in postencephalitic cases, but neurofibrillary tangles were the usual nigral cell abnormalities. Both of these cellular abnormalities appear occasionally in the substantia nigra of aged, nonparkinsonian individuals. Possibly the individuals with Lewy bodies would have developed Parkinson disease if had they lived a few more years.

Noteworthy is the finding by McGeer et al that nigral cells normally diminish with age, from a maximal complement of about 425,000 to 200,000 at age 80. Tyrosine-hydroxylase, the rate-limiting enzyme for the synthesis of dopamine, diminishes correspondingly. However, these authors and others have found that in patients with Parkinson disease, the number of pigmented neurons was reduced to 30 percent or less of that in age-matched controls. Using more refined counting techniques, Pakkenberg and coworkers estimated the average total number of pigmented neurons to be 550,000 and to be reduced in absolute numbers by 66 percent in Parkinson patients. (The number of nonpigmented neurons was reduced in Parkinson cases by only 24 percent.) Thus, aging contributes importantly to nigral cell loss, but the cell depletion is so much more marked in Parkinson disease that some factor other than aging must also be operative.

Other depletions of cells are widespread as mentioned, but they have not been quantitatively evaluated and their significance is less clear. There is neuronal loss in the mesencephalic reticular formation, near the substantia nigra. These cells project to the thalamus and limbic lobes. In the sympathetic ganglia, there is slight neuronal loss and Lewy bodies are seen. This is also true of the pigmented nuclei of the lower brainstem as well as of neuronal populations in the putamen, caudatum, pallidum, and substantia innominata. On the other hand, dopaminergic neurons that project to cortical and limbic structures, to caudate nucleus and nucleus accumbens, and to periaqueductal gray matter and spinal cord are affected little or not at all. The lack of a consistent lesion in either the striatum or the pallidum is noteworthy in view of the reciprocal connections between the striatum and the substantia nigra and the depletion of striatal dopamine, based on the loss of nigral projections, that characterizes the disease.
One hypothesis is that the inner segment of the globus pallidus by which MPTP produces the Parkinson syndrome is unsettled. The precisemechanism bound by the melanin in the dopaminergic nigral neurons insuf-
ficient concentration to destroy the cells. The primary genetic cause is an extra nonmutant copy of the synuclein gene (Singleton). Additionally, some cases of familial Parkinson disease are found in families with mutations of genes that reduce normal removal of synuclein by the proteosomes. The excess of synuclein polymerizes to form protofibrils, a process that is enhanced by defects in heat shock proteins (Hsps) or by the action of dopamine, which binds to synuclein. In turn, this leads to formation of Lewy bodies. This model attributes the neurotoxicity to either the protofibrils or the Lewy bodies. (Adapted by permission from Eriksen JL, Dawson TM, Dickson DW, Petrucelli L: Caught in the act: α-synuclein-dopamine adduct formation. Neuron 40:453–456, 2003.)

The most provocative recent discoveries have involved the nuclear and synaptic protein α-synuclein, the main component of Lewy bodies in both the sporadic and inherited forms of Parkinson disease as well as in Lewy body disease, as mentioned earlier. Synuclein normally exists in a soluble unfolded form, but in high concentrations it forms aggregates of filaments, which are the main constituent of the Lewy body. Immunostaining techniques also disclose less specific proteins, such as ubiquitin and tau, within the Lewy bodies. Furthermore, as noted earlier, in unrelated families with a rare autosomal dominant form of Parkinson disease, three different mutations on chromosome 4 code for an aberrant form of α-synuclein that decreases its stability and promotes its aggregation (Polymeropoulos et al). A family has also been described in which the primary genetic cause is an extra nonmutant copy of the α-synuclein gene (Singleton). Additionally, some cases of familial parkinsonism are found in families with mutations of genes that control the removal of α-synuclein from the cell via a proteosomal pathway. Together, these findings indicate that instability and the misfolding of α-synuclein may be the primary protein defect in these forms of Parkinson disease. In this view, somewhat analogous to the amyloid hypothesis for Alzheimer disease, the propensity to misfolding is increased by elevated levels of α-synuclein, and misfolded proteins form toxic protofibrils and then Lewy bodies. This process is accelerated by defects in heat shock proteins that chaperone α-synuclein into and out of the cell (Fig. 39-2). Curiously, Lewy bodies are not found in patients with most of the parkin

Figure 39-6. Schematic diagram of proposed mechanisms of α-synuclein toxicity in Parkinson disease. In this model, α-synuclein levels are elevated by (a) duplication of one copy of the α-synuclein gene; (b) point mutations in the α-synuclein gene that generate excessive accumulations of synuclein; or (c) mutations in parkin and UCH-L1 genes that reduce normal removal of synuclein by the proteosomes. The excess of synuclein polymerizes to form protofibrils, a process that is enhanced by defects in heat shock proteins (Hsps) or by the action of dopamine, which binds to synuclein. In turn, this leads to formation of Lewy bodies. This model attributes the neurotoxicity to either the protofibrils or the Lewy bodies. (Adapted by permission from Eriksen JL, Dawson TM, Dickson DW, Petrucelli L: Caught in the act: α-Synuclein is the culprit in Parkinson’s disease. Neuron 40:453–456, 2003.)

The statistical data relating Parkinson and Alzheimer diseases are difficult to assess because of different methods of examination from one reported series to another (Quinn et al). Nevertheless, the overlap of the two diseases is more than fortuitous, as indicated in an earlier part of this chapter. In our own pathologic material, the majority of the demented Parkinson patients showed some Alzheimer-type changes, but there were several in whom few plaques or neurofibrillary changes could be found or in whom the cortical neuronal loss was accompanied by a widespread distribution of Lewy bodies marking the process as a Lewy body dementia (see earlier discussion).

Of interest has been the observation, both in humans and in monkeys, that a neurotoxin (known as MPTP) produces irreversible signs of parkinsonism and selective destruction of cells in the substantia nigra (this is discussed further on). The toxin, an analogue of meperidine, which was self-administered by addicts, binds with high affinity to monoamine oxidase, an extraneural enzyme that transforms it to a toxic metabolite, pyridinium MPP. The latter is bound by the melanin in the dopaminergic nigral neurons in sufficient concentration to destroy the cells. The precise mechanism by which MPTP produces the Parkinson syndrome is unsettled. One hypothesis is that the inner segment of the globus pallidus
mutations. It must be emphasized, just as it was in Alzheimer disease, that no genetic error relating to synuclein has been found in patients with sporadic Parkinson disease.

Parkin is a ubiquitin protein ligase that participates in the removal of unnecessary proteins from cells through the proteosomal system (Fig. 39-6). Attachment of parkin and ubiquitin to cytosolic proteins is understood to be an obligatory step in the disposal of proteins by proteosomes. Mutations in the parkin gene lead either to an inadequacy or misfolding of synuclein, resulting in its accumulation, or to the disruption of disposal of proteins in dopamine-producing cells. The importance of the ubiquitination pathway in this disease is further highlighted by the report that parkinsonian features are present in a family with mutations in ubiquitin carboxy-terminal hydrolase L1 (UCHL-1) (Table 39-2). These relationships and the processing of synuclein in the cell are illustrated in Fig. 39-6. It must be emphasized that some of the notions illustrated are speculative or, more specifically, are derived largely from the molecular study of familial Parkinson disease and therefore may not apply to the sporadic disease. They do, however, accurately describe the pathways involved in the handling of synuclein and are therefore likely to be implicated in idiopathic Parkinson disease.

Several other gene defects are of interest in familial parkinsonism. One is a dominantly inherited mutation in the gene Nurr1, whose normal function is to specify the identity of dopaminergic neurons. Another is in recessively inherited parkinsonism due to defects in the gene DJ-1, a protein that is essential for the normal neuronal response to oxidative stress. Also, a disease-causing mutation in the gene termed “PINK,” corresponding to Park6, codes for a mitochondrial kinase, therefore implicating this cellular structure in some forms of Parkinson disease (Valente et al). Presumably, dopaminergic neurons are compromised in some manner by these defects.

It is hoped that the genetic mutations that give rise to Parkinson disease will expose the molecular pathophysiology of the disease. As discussed earlier, several sites are implicated in the familial forms of Parkinson disease, most related to the gene that codes for synuclein, the main component of the Lewy body. This conceptually links familial Parkinson disease with Alzheimer disease and possibly with ALS, all potential sequela of toxic protein aggregation. As in the aforementioned diseases, new findings suggest that soluble forms of the protein may be the toxic agent, rather than the aggregated protein within cells, or that there is an interaction between the mutated proteins and other proteins such as ubiquitin, another major component of the Lewy body. The binding of ubiquitin is a step in the degradation of intracellular proteins, and mutant parkin proteins appear to have lost this ability. In any case, the current evidence favors a role for the regulation of synuclein in the viability of dopaminergic neurons in the inherited forms of disease, and probably in the sporadic ones as well (Fig. 39-6).

**Treatment** Although there is no current treatment that halts or reverses the neuronal degeneration underlying Parkinson disease, methods are now available that afford considerable relief from symptoms. Treatment can be medical or surgical, although reliance is placed mainly on drugs, particularly on L-dopa (Table 39-4). The following sections are necessarily detailed in order to give the clinician a full comprehension of the use and side effects and interactions of these drugs.

**L-Dopa and L-Dopa–Modifying Drugs** At present, L-dihydroxyphenylalanine (L-dopa) is unquestionably the most effective agent

</table>
for the treatment of Parkinson disease, and the therapeutic results, even in those with far advanced disease, are much better than have been obtained with other drugs. As mentioned earlier, some degree of response is so nearly universal that many neurologists view responsiveness to L-dopa as a diagnostic criterion. The theoretical basis for the use of this compound rests on the observation that striatal dopamine is depleted in patients with Parkinson disease but that the remaining diseased nigral cells are still capable of producing some dopamine by taking up its precursor, L-dopa. The number of neurons in the striatum is not diminished, and they remain receptive to ingested dopamine acting through the residual nigral neurons. Over time, however, the number of remaining nigral neurons becomes inadequate and the receptivity to dopamine of the striatal target neurons becomes excessive, possibly as a result of denervation hypersensitivity; this results in both a reduced response to L-dopa and to paradoxical and excessive movements (dyskinesias) with each dose.

Most patients tolerate the drug initially and experience few serious adverse effects and will show dramatic improvement, especially in hypokinesia and tremor after several days or sooner. The side effects and limitations of L-dopa become considerable as the drug therapy continues and the disease progresses. These are discussed below.

By combining L-dopa with a decarboxylase inhibitor (carbidopa or benzerazide), which is unable to penetrate the central nervous system (CNS), decarboxylation of L-dopa to dopamine is greatly diminished in peripheral tissues. This permits a greater proportion of L-dopa to reach nigral neurons and, at the same time, reduces the peripheral side effects of L-dopa and dopamine (nausea, hypotension, etc.). Combinations of carbidopa-levodopa are available in a 1:10 or 1:4 ratio and the benzerazide-levodopa combination in a 1:4 ratio. The initial dose of levodopa-carbidopa is typically one-half to one of a 25/100-mg tablet given two or three times daily and increased slowly until optimum improvement is achieved, usually up to four tablets administered five or more times daily as the disease advances, or a similar dose of the 25/250-mg combination.

A newer class of catechol-O-methyltransferase (COMT) inhibitors, typified by entacapone, extends the plasma half-life and the duration of L-dopa effect by preventing its breakdown (as opposed to increasing its bioavailability, as in the case of carbidopa). A combination of L-dopa, carbidopa, and a COMT inhibitor has recently become available in one pill.

Long-acting preparations of levodopa-carbidopa (Sinemet-CR) may reduce dyskinesias in some patients (Hutton and Morris) in the advanced stages of disease, but our experience with these drugs given earlier in the course of disease has been less positive. In transferring a patient from conventional L-dopa/carbidopa preparations to the long-acting formulation, the frequency of administration can be roughly halved while the total amount of L-dopa initially remains unchanged. The absorption of the long-acting drug, however, is approximately 70 percent, often necessitating a slight increase in total dose. To facilitate the treatment of morning rigidity and tremor, the long-acting tablet can be broken in half to speed absorption or a small dose of conventional medication can be given at the same time.

**Dopamine Agonists** These drugs have a direct dopaminergic effect on striatal neurons, thereby partially bypassing the depleted nigral neurons. They have found a place both as the initial treatment in the early phases of disease, replacing L-dopa in this role, and in modifying the effects of L-dopa later in the illness. In both cases, they are favored because they are associated with fewer dyskinetic motor complications and also because of a putative neuroprotective effect that is alleged to slow the progress of disease (see below). Bromocriptine, pergolide, and lisuride are synthetic ergot derivatives whose action in Parkinson disease is explained by their direct stimulating effect on dopamine (D2) receptors located on striate neurons. The nonergot dopamine agonists ropinirole and pramipexole have a similar type and duration of effectiveness. However, it should be pointed out that dopamine agonists are consistently less potent than L-dopa in managing the main features of Parkinson disease and, in higher doses, they produce similar side effects (see further on).

Representative of studies using dopamine agonists, Rascol and colleagues reported that the use of ropinirole during the first 5 years of illness controlled the symptoms satisfactorily and, in addition, reduced the incidence of dyskinesias compared to treatment with L-dopa. Why dyskinesias are less frequent with ropinirole than with L-dopa is not known. Some specialists attribute this simply to their lower potency. All these drugs should be introduced cautiously. For example, the initial dose of pramipexole is 0.125 mg three times daily, following which the dosage is doubled weekly to a total of 3 to 4.5 mg per day if the medication is used without L-dopa. Bromocriptine therapy begins at 7.5 to 10 mg daily in three to four divided doses, and the dosage is increased very slowly to an optimal level of 40 to 60 mg daily. With all of these drugs it is possible to gradually reduce levodopa-carbidopa by about 50 percent. (A dose of 5 to 10 mg of bromocriptine is approximately equivalent to 25/100 mg carbidopa/levodopa.) Their duration of action is slightly longer than that of L-dopa and they cause less nausea, but otherwise the action and side effects of the two drugs are much the same, as noted. These medications are also undoubtedly useful in smoothing the effects of L-dopa. The addition of small doses of one of these agents to a stable regimen of L-dopa in order to reduce dyskinesias requires careful titration over several weeks and a reduction of the total L-dopa dose (see further on).

Our experience is in general agreement with that of Marsden, who found that of 263 patients given dopamine agonists as the sole treatment, all but 82 had abandoned medication after 6 months because of lack of effect or adverse reactions. Nevertheless, the fact that a large enough proportion of patients continue to benefit for up to 3 to 5 years indicates that the initial use of dopamine agonists has merit.

Even small doses of these drugs, when first introduced, may induce a prolonged episode of hypotension or orthostatic hypotension, but most patients are quite tolerant of them. They may also produce abrupt and unpredictable sleepiness, and patients should be warned of this possibility in relation to driving. More data are required to judge the efficacy of the current trend of initiating therapy with a dopamine agonist rather than with L-dopa.

**Anticholinergic Agents and Other Alternatives to L-Dopa and Dopamine Agonists** Because of the side effects of levodopa and of dopaminergic agents, some neurologists avoid all types of pharmacotherapy if the patient is in the early phase of the disease and the parkinsonian symptoms are not troublesome. When the predominant manifestation is tremor, very satisfactory results can be obtained in some patients for up to several years with anticholinergic agents alone. The anticholinergic drugs have little effect on the postural, hypokinetic, and other manifestations of disease. Koller’s study, which quantified the effect of anticholinergic medication on tremor and compared it to L-dopa, concluded that there was variability in response between patients but that L-dopa was
on average more effective. Nonetheless, anticholinergic agents have long been in use for the treatment of tremor in younger patients and we still use them occasionally, either in conjunction with L-dopa or in patients who cannot tolerate the latter drug. The optimum dosage level is the point at which the greatest relief from tremor is achieved within the limits of tolerable side effects, mainly dry mouth. In older patients, one must be alert to changes in cognitive function, hallucinations, and prostatic obstruction.

Several synthetic preparations of anticholinergic drugs are available, the most widely used ones being trihexyphenidyl (Artane, beginning with 1 to 2 mg per day and increased up to 6 to 8 mg over several weeks) and benztropine mesylate (Cogentin, 1 to 4 mg per day in divided doses). When tremor is the most prominent symptom, we have also had success with the related agent ethopropazine (50 to 200 mg daily in divided doses; Parsidol, Parsitane). The effects on tremor are cumulative and may not be evident for several days. In order to obtain maximum benefit from the use of these drugs, they should be given in gradually increasing dosage to the point where toxic effects appear: dryness of the mouth (which can be beneficial when drooling of saliva is a problem), blurring of vision from pupillary mydriasis, constipation, and urinary retention (especially with prostatism). Tremor abates in several days and most of our patients have become tolerant to the dry mouth after several weeks. Pyridostigmine, propantheline, or glycopyrrrolate can be given to reduce the dryness.

With higher dose ranges, mental slowing, confusional states, hallucinations, and impairment of memory in elderly patients—specifically if there is already some degree of forgetfulness—are side effects that limit usefulness. Occasionally, further benefit may accrue from the addition of another antihistaminic drug, such as diphenhydramine or phendindamine.

The antiviral agent amantadine (Symmetrel, 100 mg twice daily) has mild or moderate benefit for tremor, hypokinesia, and postural symptoms. In some patients it reduces L-dopa–induced dyskinesias (see further on). Its mechanism of action is not known but is thought to be through antagonism of N-methyl-D-aspartate (NMDA). It should be noted that amantadine commonly causes leg swelling, may worsen congestive heart failure, and can have an adverse effect on glaucoma as well as exacerbating the cognitive changes associated with anticholinergic medications.

Carbidopa/levodopa or an agonist preparation is introduced only when the symptoms begin to interfere with work and social life or falling becomes a threat, and then these drugs are used at the lowest possible dose.

**Slowing the Progression of Disease (“Neuroprotective” Effects of Medication)** Another approach, now controversial, had been to initiate the treatment of patients with newly diagnosed Parkinson disease with the monoamine oxidase inhibitor selegiline, 5 mg twice daily, and to continue its use until symptoms become disabling, at which point L-dopa or a dopamine agonist is introduced. Selegiline inhibits the intracerebral metabolic degradation of dopamine, and clinical trials conducted by the Parkinson Study Group have suggested that it slows progression of the disease in its early stages. Subsequent observations, however, have not fully corroborated this claim. We use it sparingly, but some authoritative clinicians find it useful.

Following this same line of reasoning, several studies, most still disputed or unconfirmed, have suggested that ropinirole, pramipexole, and even L-dopa have “neuroprotective” effects in Parkinson disease. Also, the proposal that the progression of symptoms, as measured by a variety of scales, is slowed has not been fully corroborated. Technical problems in interpreting these results are discussed at length in the reviews by Wooten and by Clarke and Guttmann. The uncertainties here have to do with clinical grading systems, functional imaging techniques, and points of comparison to treatment with L-dopa. Nevertheless, in the last few years these observations have led to the promotion of dopamine agonists as the initial therapy.

The notion that the administration of L-dopa early in the disease might reduce the period over which it remains effective has been largely dispelled, but some neurologists continue to adhere to it. Cederman et al, who reviewed the course of the illness in 307 patients over a 7-year period, found no evidence that the early initiation of L-dopa treatment predisposed to the development of fluctuations in motor response or to dyskinesia and dementia. In discussing this with patients, we point out the findings of the “Ell-dopa” trial by the Parkinson Study Group: in 361 individuals with Parkinson disease of less than 2 years duration who were treated with L-dopa for 40 weeks and then had the medication withdrawn, functional and other measures were better than in those who received no medication. That is, L-dopa may have itself been neuroprotective. Also, the large multicenter study reported by Diamond et al indicated that patients who were given L-dopa early in the disease actually survived longer and with less disability than those who began the medication late in the course. These results emphasize the difficulty of assessing the protective effect of various drugs.

Finally, attempts to slow the disease by vitamin antioxidants such as vitamin E have met with mixed but generally negative results. A possible exception has been the trial of coenzyme Q10 by Shults and colleagues. Massive doses of this agent, 1200 mg per day, were found to offer some marginal advantages on the progression over 6 to 18 months as measured by certain standard scores of overall daily function but not on most neurologic scales. Further study of this approach is advised. For the moment, unless it presents a financial burden, the use of this agent seems reasonable but not obligatory.

**Side Effects of L-Dopa Treatment** As already mentioned, the side effects of L-dopa are at times significant to the degree that its continuation cannot be tolerated. Some patients are at first troubled by nausea, although this can be mitigated by taking the medication with meals. A few have mild orthostatic hypotensive episodes. Nausea usually disappears after several weeks of continued use or can be allayed by the specific dopaminergic chemoreceptor antagonist domperidone.

However, the most troublesome effects of L-dopa as the disease advances, usually after several years of treatment, are an end-of-dose reduction in efficacy (and the more precipitous “on-off” phenomenon) and the induction of involuntary “dyskinetic” movements—restlessness, head wagging, grimacing, lingual-labial dyskinesia, and especially choreoathetosis and dystonia of the limbs, neck, and trunk. A decline in efficacy after the usual 2 to 4 h may be treated by more frequent dosing or the addition of a COMT inhibitor.

The on-off phenomenon is a rapid and sometimes unpredictable change in the patient, in a matter of minutes or from one hour to the next, from a state of relative freedom from symptoms to one of complete or nearly complete immobility. Both dyskinesias and severe “off” periods eventually appear in about 75 percent of patients within 5 years. Above a certain daily dose level of L-dopa, which varies from patient to patient, very few patients escape these effects, forcing an increased frequency of administration and usually a reduction in dosage.
If involuntary movements are induced by relatively small doses of L-dopa, the problem may be suppressed to some extent by the addition of direct-acting dopaminergic agents or by the concurrent administration of amantadine. The use of lower doses of long-acting preparations of L-dopa may also be helpful in reducing dyskinesias, and the atypical antipsychotic medications have been said to be useful.

The onset of psychiatric symptoms coincident with the use of L-dopa may also present problems and is to be expected eventually in 15 to 25 percent of patients, particularly in the elderly. Depression, although frequent, is only occasionally a serious problem, even to the point of suicide. Delusional thinking may also occur in these circumstances. This combination of movement and psychiatric disorders is difficult to treat, and one is faced with instituting an antidepressant regimen or perhaps using one of the newer class of antipsychotic medications that have the least extrapyramidal side effects (see below and Chap. 50). While the selective serotonin reuptake inhibitors have been useful in cases of apathetic depression, they may cause slight worsening of parkinsonian symptoms. In our hands, trazodone has been most helpful in treating depression and insomnia, the latter also being a major problem in some patients. Excitement and aggressiveness appear in a few. A return of libido may lead to sexual assertiveness.

Confusion and outright psychosis (hallucinations and delusions) are seen in advanced cases of Parkinson disease when high doses of L-dopa are required and the disease has been present for many years. This may first be treated by attempting to reduce the dose of the drug. If this is not tolerated, the atypical neuroleptics olanzapine, clozapine, risperidone, or quetiapine in low doses are recommended by Friedman and Lannon. The side effects of these drugs include sleepiness, orthostatic hypotension, and sialorrhea. As noted above, clozapine has been said to provide an additional benefit of suppressing dyskinesias in advanced Parkinson disease (Bennett et al), but it requires surveillance of the white blood cell count because of the idiosyncratic occurrence of agranulocytosis in up to 2 percent of patients. Although useful in the treatment of frankly psychotic patients, these drugs tend to be far less effective once dementia has supervened. The anticonvulsant valproate is also said to be useful in this circumstance, but in our hands it has not been as effective as clozapine and related drugs. Despite their lesser tendency to produce rigidity, olanzapine and probably the other similar agents in high doses may slightly worsen motor disability.

An important note of warning: anticholinergic agents or L-dopa should not be discontinued abruptly in advanced Parkinson disease. If this is done, the patient may become totally immobilized by a sudden and severe increase of tremor and rigidity; rarely, a neuroleptic syndrome, sometimes fatal, has been induced by such withdrawal. Reducing the medication dose over a week or so is usually adequate.

With progressive loss of nigral cells, there is an increasing inability to store L-dopa and periods of drug effectiveness become shorter. In some instances, the patient becomes so sensitive to L-dopa that as slight an excess as 50 to 100 mg will precipitate choreoathetosis; if the dose is lowered by the same amount, the patient may develop disabling rigidity. With the end-of-dose loss of effectiveness and on-off phenomenon, which with time become increasingly frequent and unpredictable, the patient may experience pain, respiratory distress, akathisia, depression, anxiety, and even hallucinations. Some patients function quite well in the morning and much less well in the afternoon, or vice versa. In such cases, and for end-of-dose and on-off phenomena, one must titrate the dose of L-dopa and utilize more frequent doses during the 24-h day; combining it with a dopamine agonist or a long-acting preparation may be helpful. Sometimes temporarily withdrawing L-dopa and at the same time substituting other medications may reduce the on-off phenomenon.

Based on the notion that alimentary-derived amino acids antagonize the clinical effects of L-dopa, the use of a low-protein diet has been advocated as a means of controlling the motor fluctuations described above (Pincus and Barry). Symptoms can sometimes be reduced by the simple expedient of eliminating dietary protein from breakfast and lunch. Moreover, this dietary regimen may permit the patient to reduce slightly the total daily dose of L-dopa. Such dietary manipulation is worth trying in appropriate patients; it is not harmful, and most of our patients with advance disease who have persisted with this diet have reported improvement in their symptoms or an enhanced effect of L-dopa.

**Surgical Measures**

Until recently, success with L-dopa had practically replaced the use of the ablative surgical therapy pioneered by Cooper. This involved the stereotactic placement of lesions in either the globus pallidus, ventrolateral thalamus, or subthalamic nucleus, contralateral to the side of the body chiefly affected. The best results were obtained in relatively young patients, in whom unilateral tremor or rigidity rather than akinesia were predominant. The symptoms that responded least well to operation (and indeed to treatment with L-dopa) in Cooper’s patients were postural imbalance and instability, paroxysmal akinesia, bladder and bowel disturbances, dystonia, and speech difficulties.

In the last two decades, through the work of Laitinen and others, this mode of therapy has been revived and advanced by the newer technique of implanted electrical stimulators. Both the ablative approach and the implantation of electrodes involve the placement, under precise stereotactic control, of a lesion or a wire in the posterior and ventral (medial) part of the subthalamic nucleus or the globus pallidus. Improvement of parkinsonian symptoms is reliably effected, particularly on the side opposite the procedure. Also, there is in most patients an enhanced responsiveness to L-dopa and a reduction of drug-induced dyskinesias. In patients who have been studied for more than a few years after the unilateral ablative procedure, the beneficial effects on dyskinesias contralateral to the operation are sustained to some extent, but not in the ipsilateral limbs. The improvement in “off-state” bradykinesia is lost after 2 or so years and any betterment in axial rigidity and imbalance abates in many patients within a year of operation, as reported by Gregory and by Lang et al. In a randomized trial comparing pallidotomy to continued medical treatment of patients with dyskinesias, bradykinesia, or severe fluctuations in response to L-dopa, de Bie and colleagues demonstrated a clear improvement in motor function after surgery, while the group treated with medication continued to worsen. These improvements are in part due to the ability to reduce the dose of L-dopa. Most groups have abandoned the pallidum as a surgical target in favor of the subthalamic nucleus.

The technique of high-frequency electrical stimulation has given probably better results than surgical ablation. It is now used almost exclusively. In particular, stimulation of the subthalamic nucleus has produced improvement in all features of the disease but least all in gait and balance (Limousin et al). A study by The Deep-Brain Stimulation for Parkinson’s Disease Group has demonstrated at least short-term benefit in motor fluctuations after the bilateral implantation of stimulating electrodes in both subthalamic nuclei, but the durability of this effect is not known. The patients
chosen were those who had failed to derive benefit from medica-
tions. The benefit with bilateral stimulation of the globus pallidus
was somewhat less. Several groups have pointed out that cognitive
function is not improved and may even decline.

The ideal patient for deep-brain stimulation is currently con-
sidered to be an individual who, to maintain mobility, requires a
dose of L-dopa that produces unacceptable dyskinesias and who is
continually cycling between on and off periods. Dystonia, when
present as part of the native disease or as a result of medication,
may also benefit by this treatment. However, some patients appear
to do very well with the introduction of brain stimulation early in
the course of illness.

Presumably, the high-frequency electrical impulses cause a
localization of local neuronal activity that is the functional equivalent
to an ablative lesion, but the effects may be more complex by way
of stimulating neurotransmitter release.

The observed improvement in the L-dopa-induced dyskinesias
has recently led to the earlier more liberal use of subthalamic stimu-
lators. But as with ablative surgery, the durability of the benefit
is uncertain. Readjustment of the frequency of the stimulus and
breakage of the wire are minor problems. Hemorrhage into the
basal ganglia and local infection near the stimulator has occurred in
a small number of patients so treated.

The cerebral implantation of embryonic adrenal medullary tis-
sue from 8- to 10-week-old human fetuses has provided a modest
but undeniable improvement in motor function (Spencer et al,
Freed et al), and some patients also appear to have benefited from the
striatal implantation of human fetal and porcine nigral cells and
autologous adrenal cells. The study by Freed and colleagues found
a small improvement on a global scale that measures functional,
psychologic, and neurologic aspects only in younger patients.
These procedures are hampered by many difficulties, mainly in
obtaining tissue and the failure of grafts to survive but also the
problem of uncontrollable dyskinesias in some patients. Much of
the enthusiasm for these procedures has temporarily subsided. In-
vestigation into their possible usefulness continues.

Other Ancillary Treatments Finally, in the management of the
patient with Parkinson disease, one must not neglect the mainte-
nance of optimum general health and neuromuscular efficiency by
a planned program of exercise, activity, and rest; expert physical
therapy and exercises such as those performed in yoga may be of
help in achieving these ends. Sleep may be aided by the soporific
antidepressants. Postural imbalance and falls can be greatly miti-
gated by the use of a cane or walking frame. A number of excellent
exercise programs have been devised specifically for patients with
Parkinson disease, and measures such as massage and yoga have
their advocates. Our position has been that any activity that keeps
the patient active and committed is of great value. Speech exercises
help the motivated patient. Hypotensive episodes respond to
0.5 mg of fludrocortisone (Florelin) each morning. Focal dystonias
of the foot are partially treatable with local injections of botulinum
toxin. In addition, the patient often needs a great deal of emotional
support in dealing with the stress of the illness, in comprehending
its nature, and in carrying on courageously in spite of it.

Striatal Degeneration, Shy-Drager
Syndrome, and Multiple System
Atrophy

Closely related to Parkinson disease but with a different pathologic
basis is a state designated by Adams and colleagues as striatonigral
degeneration. The pathologic changes were found by chance in
four middle-aged patients, none with a family history of similar
disease, in three of whom a parkinsonian syndrome had been de-
scribed clinically. In one of the three, who had been examined
carefully, the typical rigidity, stiffness, and akinesia had begun on
one side of the body, then spread to the other, and progressed over
a 5-year period, but with little or none of the characteristic tremor
of idiopathic Parkinson disease. A flexed posture of the trunk and
limbs, slowness of all movements, poor balance, mumbling speech,
and a tendency to faint when standing were other elements in the
clinical picture. Mental function was intact, and there were no re-
flex changes, no suck and grasp reflexes, and no cerebellar signs
or involuntary movements. The other two patients had been seen
by competent neurologists who had made a diagnosis of Parkinson
disease. Some of the symptoms had been partially relieved by an-
ticholinergic drugs. There was an early-onset cerebellar ataxia in
the fourth patient, later obscured by a Parkinson syndrome.

In each case the postmortem examination disclosed extensive
loss of neurons in the zona compacta of the substantia nigra, but
notably there were no Lewy bodies or neurofibrillary tangles in the
remaining cells. Even more striking were the degenerative changes
in the putamina and to a lesser extent in the caudate nuclei. These
structures were greatly reduced in size and had lost most of their
neurons—more of the small than the large ones and more on the
side opposite the first clinical symptoms. The findings were sug-
gestive of the striatal lesions of Huntington chorea except that the
cell loss was greater in the putamen than in the caudatum. Second-
ary pallidal atrophy (mainly a loss of striopallidal fibers) was
present. In the fourth patient there was, in addition, an advanced
olivopontocerebellar degeneration.

Following the original report, in 1964, many patients were
recognized in whom the changes of striatonigral and olivoponto-
cerebellar degeneration were combined and in some of whom the
symptoms and signs of cerebellar ataxia actually preceded the par-
kinsonian manifestations. Equally frequent was a predominantly
extrapyramidal syndrome accompanied by autonomic insuffi-
ciency, as described below.

Shy-Drager Syndrome Nearly half of the patients with striato-
nigral degeneration are handicapped by orthostatic hypotension,
which proves at autopsy to be associated with loss of intermedio-
lateral horn cells and of pigmented nuclei of the brainstem. This
combined parkinsonian and autonomic disorder, still referred to as
the Shy-Drager syndrome, has been mentioned in the chapters on
fainting and the autonomic nervous system (pages 326 and 463).
In addition to orthostatic hypotension, symptoms of failure of au-
tonomic control include impotence, loss of sweating, dry mouth,
miosis, and urinary retention or incontinence. Vocal cord palsy is
an important and sometimes initial manifestation of the autonomic
disorder. It causes dysphonia or stridor and airway obstruction re-
quiring tracheostomy (see page 463). A dusky discoloration of the
hands that has been ascribed to poor control of cutaneous blood
flow has been emphasized by Klein and colleagues, but we have
not seen it in our patients. It should be noted that orthostatic hy-
potension is also observed in up to 15 percent of patients with
idiopathic Parkinson disease, sometimes exaggerated by medica-
tions, but the degree of drop in blood pressure is far greater and
more consistent in patients with this form of multiplet system
atrophy.

Multiple System Atrophy Because of the recognition that the
clinical and pathologic features of sporadic striatonigral degenera-
tion, with or without autonomic failure, and in some instances
those of olivopontocerebellar atrophy often coexist, each component expressing itself variably in any individual. Graham and Oppenheimer in 1969 proposed the term multiple system atrophy (MSA), which has gained wide acceptance. Several large series of cases of this complex syndrome have now been published, providing a perspective on the frequency and nature of its components. Aside perhaps from a unifying feature of glial and neuronal inclusions described below, the syndromes in which parkinsonism and cerebellar ataxia are prominent are quite different from each other on clinical grounds, for which reason we prefer to apply the term MSA only to cases displaying both features. Others have categorized them as MSA-P and MSA-C, depending on whether they display predominantly parkinsonism or cerebellar ataxia. In this nosology, cases in which autonomic failure as described above predominate might be denominated as MSA-A.

In the Brain Tissue Bank of the Parkinson Disease Society of Great Britain, MSA accounted for 13 percent of patients who had been identified during life as having idiopathic Parkinson disease. All of the patients with MSA had one or more symptoms of autonomic failure (postural hypotension, urinary urgency or retention, urinary or fecal incontinence, impotence) and dysphonia or stridor. Babinski signs were present in half the patients and cerebellar ataxia in one-third. Tremor was rare. Males were affected more often than females. In a comparable series of 100 patients (67 men and 33 women) studied by Wenning and coworkers, the disease began with a striatonigral-parkinsonian syndrome in 46 percent; often it was asymmetrical to begin with. Mild tremor was detected in 29 percent, but in only a few was it of the “resting” Parkinson type. In another 41 percent the illness began with autonomic manifestations; orthostatic hypotension occurred eventually in almost all patients, but it was disabling in only a few. Cerebellar features dominated the initial stages of the disease in only 5 percent, but ataxia was eventually obvious in half the group. This presentation will be elaborated further in the section on the degenerative cerebellar ataxias. The extrapyramidal illness, on the whole, was more severe than Parkinson disease, since more than 40 percent of patients were confined to a wheelchair or otherwise severely disabled within 5 years. These observations generally match the findings in a group of 188 patients described by Quinn and colleagues. In that series, pyramidal signs were present in 60 percent and autonomic features in 77 percent, a feature we have found helpful in diagnosis and one that certainly marks the illness as affecting multiple systems.

Colosimo and colleagues, who reviewed the clinical findings in 16 pathologically verified cases of MSA, found that several signs—namely, the relative symmetry of the signs and rapid course, the lack of response to L-dopa and absence or minimal amount of tremor, and the presence of autonomic disorders—reliably distinguished this syndrome from Parkinson disease. These observations are in keeping with our own, and we would add that abnormalities of eye movement are not prominent in MSA. Additional odd features, especially dystonia, are remarked upon in other series; anterocollis or dystonia of the lower facial muscles, for example, are striking in a few cases. It is noteworthy that levodopa has had little or no effect or has made these patients worse early in the disease, but we have seen exceptions. This is probably attributable to the loss of striatal dopamine receptors.

The diagnosis of MSA has been aided to some extent by imaging techniques. Both MRI and CT scans frequently show atrophy of the cerebellum and pons in those with cerebellar features. The putamina are hypodense on T2-weighted MRI and may show an increased deposition of iron. Studies with PET have disclosed an impairment of glucose metabolism in the striatum and to a lesser extent in the frontal cortex—a reflection, no doubt, of the loss of functioning neuronal elements in these parts. Finally, it should be repeated that, despite the frequent concurrence of striatonigral degeneration, olivopontocerebellar degeneration, and the Shy-Drager syndrome, each of these disorders occurs in pure or almost isolated form; we therefore prefer to retain their original designations. This distinction was reflected in the findings of Gilman et al, who followed a series of 51 patients with olivopontocerebellar atrophy for up to 10 years; only 17 of their patients acquired a parkinsonian syndrome or autonomic failure.

Pathology In recent years, attention has been drawn to the presence of abnormal staining material in the cytoplasm of astroglia and oligodendrocytes and in some neurons as well. These cytoplasmic aggregates have been referred to as glial cytoplasmic inclusions (Papp et al). Although they bear little resemblance morphologically to other discrete inclusions that have come to be accepted as characteristic of certain degenerative CNS diseases (e.g., Lewy bodies) they nonetheless contain α-synuclein (which is the main component of Lewy bodies). It is not clear to us whether these glial cytoplasmic accumulations represent a histopathologic hallmark of sporadic cases of MSA (Chin and Goldman; Lantos), since their presence is not specific; they have been identified in practically every degenerative disease that has been subjected to sensitive silver impregnation stains (Gallyas silver technique). By the same token, α-synuclein–positive inclusions have been detected in several neurodegenerative syndromes. Appropriate control studies to determine whether the glial inclusions are found in nondegenerative lesions in brain (at the edge of an infarct, for example) are needed. Also lacking is information about the frequency of these cytoplasmic inclusions in relation to the aging brain. The fundamental question remains unanswered: Do the cytoplasmic glial aggregates play a central role in the genesis of this and the other degenerative diseases, or are they simply some form of detritus that accumulates in glia as a reaction to or a by-product of the basic abnormality—namely, the wasting and loss of neurons?

**Progressive Supranuclear Palsy (PSP)**

In 1963 Richardson, Steele, and Olszewski crystallized medical thought about a clinicopathologic entity—progressive supranuclear palsy, or PSP—to which there had been only ambiguous reference in the past. The condition is not rare or unusual. By 1972, when Steele reviewed the subject, 73 cases (22 with postmortem examinations) had been described in the medical literature, and several examples are to be found in every large neurologic center; the present authors encounter approximately five new cases yearly, most of them not previously diagnosed. Rare familial clusters have been described in which the pattern of inheritance is compatible with autosomal dominant transmission (Brown et al; de Yébenes et al). No toxic, encephalitic, racial, or geographic factor has been incriminated.

**Clinical Features** Characteristically the disease has its onset in the sixth decade (range 45 to 75 years), with some combination of difficulty in balance, abrupt falls, visual and ocular disturbances, slurred speech, dysphagia, and vague changes in personality, sometimes with an apprehensiveness and fretfulness suggestive of an agitated depression. The most common early complaint is unsteadiness of gait and unexplained falling. At first, the neurologic and
ophthalmologic examinations may be unrevealing, and it may take a year or longer for the characteristic syndrome—comprising supranuclear ophthalmoplegia, pseudobulbar palsy, and axial dystonia—to develop fully.

Difficulty in voluntary vertical movement of the eyes, often downward but sometimes only upward, and late impairment of voluntary saccades are characteristic in more than half of the cases. A related but more subtle sign has been the finding of hypometric saccades in response to an optokinetic drum or striped cloth moving vertically in one direction (usually best seen with stripes moving downward). Later, both the ocular pursuit and refixation movements diminish and eventually all voluntary eye movements are lost, first the vertical ones and then the horizontal ones as well. However, if the eyes are fixated on a target and the head is turned, full movements can be obtained, proving the supranuclear, non-paralytic character of the gaze disorder. Other prominent oculomotor signs are sudden jerks of the eyes during fixation, cogwheel pursuit movements, and hypometric saccades of long duration (Troost and Daroff). Bell’s phenomenon (reflexive upturning of eyes on forced closure of the eyelids) and the ability to converge are also lost eventually, and the pupils then become small. The upper eyelids may be retracted, and the wide-eyed, unblinking stare, imparting an expression of perpetual surprise, is characteristic. Blepharospasm and involuntary eye closure are prominent in some cases. In the late stages, the eyes may be fixed centrally, and all oculocephalic and vestibular reflexes may be lost as well. It should be emphasized, however, that a proportion of patients do not demonstrate these eye signs for a year or more after the onset of the illness. We have also followed several patients who had no disorder of eye movement during life but in whom the typical pathologic changes of PSP were found unexpectedly. In one such patient there was a subcortical type of dementia; in another, focal limb dystonia and parkinsonism. Furthermore, in a few cases, several other degenerative conditions manifest a supranuclear vertical gaze disorder, although never to the extent seen in PSP; these include mainly corticobasal-ganglionic degeneration, Lewy body disease, and Parkinson disease.

The gait disturbance and repeated falling have proved difficult to analyze. Walking becomes more and more awkward and tentative; the patient has a tendency to totter and fall repeatedly but has no ataxia of the limbs, Romberg sign, or orthostatic tremor. Some patients tend to lean and fall backward (retropulsion). One of our patients, a large man, fell repeatedly, wrecking household furniture as he went down, yet careful examination provided no clue as to the basic defect in this “toppling phenomenon.”

Along with the oculomotor and balance disorders, there is a gradual stiffening and extension of the neck (in one of our patients it was sharply flexed), but this is not an invariable finding. The face acquires a staring, “worried” expression with a furrowed brow and rigid demeanor, made more striking by the paucity of eye movements. A number of our patients have displayed mild dystonic postures of a hand or foot, especially as the illness advanced but occasionally early on. The limbs may be slightly stiff, and there are Babinski signs in a few cases.

The stiffness, slowness of movement, difficulty in turning and sitting down, and hypomimia may suggest a diagnosis of Parkinson disease. However, the facial expression of the PSP patient is more a matter of tonic grimace than of lack of movement, and the lack of tremor, the erect rather than stooped posture, and prominence of oculomotor abnormalities also serve to distinguish the two disorders. The signs of pseudobulbar palsy are eventually prominent, and this feature, along with the eye movements, distinguishes the process most conspicuously from other degenerative conditions. The face becomes less expressive (“masked”), speech is slurred, the mouth tends to be held open, and swallowing is difficult. Forced laughing and crying, said to be infrequent, have been present in about half of our cases. Many patients complain of sleep disturbances. The total sleep time and rapid-eye-movement (REM) sleep are reduced, and spontaneous awakenings during the night are more frequent and longer than in normal individuals of the same age.

Other features—such as focal limb dystonia, palilalia, myoclonus, chorea, orofacial dyskinesias, and disturbances of vestibular function—are observed in some cases. Finally the patient becomes anarthric, immobile, and quite helpless. Complaints of urinary frequency and urgency have been very frequent in advanced cases under our care. Dementia of some degree is probably present in many cases but is mild in most. Some patients do eventually become forgetful and appear apathetic and slow in thinking; many others are irritable or at times euphoric.

By MRI, one can, in advanced cases, visualize the atrophy of the dorsal mesencephalon (superior colliculi, red nuclei), giving rise to a “mouse ears” configuration, but these changes may be difficult to detect. The CSF remains normal.

Although most cases of PSP are sporadic, the disease can be familial. Rojo and coworkers have described 12 pathologically confirmed pedigrees. The mode of inheritance is thought to be autosomal dominant with incomplete penetrance. The authors made note of the variable phenotypic expression of the disease even within a single pedigree.

Postmortem examinations have disclosed a bilateral loss of neurons and gliosis in the periaqueductal gray matter, superior colliculus, subthalamus, subnucleus of Luys, red nucleus, pallidum, dentate nucleus, and pretectal and vestibular nuclei, and to some extent in the oculomotor nucleus. The expected loss of the myelinated fiber bundles arising from these nuclear structures has been observed. A remarkable finding has been the neurofibrillary degeneration of many of the residual neurons. The neurofibrillary tangles are thick and often composed of single strands, either twisted or in parallel arrangement. The neurons of the cerebral cortex have been involved in some cases (shown by staining of tau protein), but these changes apparently do not correlate with dementia. The cerebellar cortex is usually spared.

The cause and nature of this disease are quite obscure. Conceivably, some cases originally considered to be instances of postencephalitic parkinsonism were examples of PSP. Studies with PET have demonstrated a decrease in blood flow—most marked in the frontal lobes—and a lesser extent of oxygen utilization in central structures (Leenders et al). Striatal dopamine formation and storage have been significantly decreased compared with control values. Much current interest has been directed to the neurofibrillary tangles and tau deposition in PSP and a potential link to the tau pathology displayed in frontotemporal dementia and in corticobasal-ganglionic degeneration (see below). As summarized by Golbe, certain tau gene haplotypes on chromosome 17p (the same site implicated in familial frontotemporal dementia) are more often associated with PSP than in unaffected individuals, but other factors, environmental or genetic, must also be involved. It is intriguing that the tau-gene haplotype of frontotemporal dementia is not found in PSP.

PSP should be suspected whenever an older adult inexplicably develops a state of imbalance, frequent falls with preserved consciousness, and variable extrapyramidal symptoms, particularly
dystonia of the neck, ocular palsies, or a picture resembling pseudobulbar palsy. If the classic abnormalities of eye movements are present, the diagnosis is not difficult. When only a parkinsonian syndrome without tremor is present, the main diagnostic consideration is striatoniqral degeneration or the corticobasal-ganglionic syndrome, described below.

Treatment

L-Dopa has been of slight but unsustained benefit in some of our patients, and combinations of L-dopa and anticholinergic drugs have been entirely ineffective in others. A marked response to these drugs should, of course, suggest the diagnosis of Parkinson disease. Recently, the drug zolpidem, a GABA-ergic agonist of benzodiazepine receptors, has been reported to ameliorate the akinesia and rigidity of PSP (Daniele et al); however, these observations require corroboration. Benztropine or trihexyphenidyl have been somewhat helpful in reducing dystonia but botulinum injections may be a better alternative if there is focal affection. Treatment of the sleep difficulties and urinary incontinence are of great assistance to the patient and family. A feeding tube becomes necessary in advanced cases.

Corticobasal-Ganglionic Syndromes

Over the years, the authors have observed several elderly patients, both men and women, in whom the essential abnormality was a progressive asymmetrical extrapyramidal rigidity combined with signs of corticospinal disease. Sometimes a mild postural action tremor (beginning unilaterally and suggestive in some respects of Parkinson disease) was added. The parkinsonism is generally unresponsive to L-dopa. These cases have come to be known on our neurology service by the names corticobasal-ganglionic or cortical-basal degeneration. The clinical relation of such cases to corticostriatospinal degeneration, described earlier, is indeterminate, and more interesting, based on the finding of tau inclusions, is a possible biologic relationship to frontotemporal dementia, Pick disease, and to progressive supranuclear palsy, as noted above.

The patients, though able to exert considerable muscle power, cannot effectively direct their voluntary actions. Attempts to move a limb to accomplish some purposeful act might result in a totally inappropriate movement, always with great enhancement of rigidity in the limb and in other affected parts, or the limb may drift off and assume an odd posture, such as a persistent elevation of the arm without the patient’s awareness—a kind of involuntary cataplexy. The disorder of limb function has some of the attributes of a limb-kinetic or an ideomotor apraxia (see Chap. 3), but the hand postures, involuntary movements, and changes in tone are at times more reminiscent of what has been described as “the alien hand.” Some patients exhibit an anosognosia. Babinski signs, impaired eyelid or ocular motion (up-gaze paresis or abnormal saccadic movements), or lingual dyskinesias, frontal release signs, and dysarthria occur in some affected individuals. Another distinct group had dementia as an early feature, as described by Grimes and colleagues.

With progression of the disease, the limbs—first on one side of the body and then on both—and the cranial muscles become involved; apraxia and variable combinations of rigidity, bradykinesia, hemiparesis, sensory ataxia, and postural and action tremor and sometimes myoclonic jerking finally render the patient helpless—unable to sit, stand, speak, or take care of basic needs. Apraxia of gaze, eyelid opening and closure, and stimulus-sensitive myoclonus appear in some cases. Mental deterioration occurs late and only in some cases. Occasionally, there is some involvement of lower motor neurons with resulting amyotrophy. Two of our patients had myoclonus as an early feature, one displaying it only on one side of the face, the other in an arm. The condition progresses for 5 years or more before some medical complication overtakes the patient.

Wenning and colleagues have described a series of 14 such patients in whom the diagnosis was confirmed at postmortem examination. The most common early symptom was an asymmetrical clumsiness of the limbs, in half of the patients with rigidity and in one-fifth with tremor; these features are now considered to be the most characteristic early features of the process. As the illness progressed, almost all the patients developed an asymmetrical or unilateral akinesic-rigid syndrome, which may be considered the essential motor disorder of this disease; various forms of gait disorder; and dysarthria. Stimulus-induced or spontaneous myoclonus and pyramidal signs, mentioned in other reports and frequent in our cases, were not prominent, and fewer than half the patients exhibited an alien-hand phenomenon; limitations of vertical gaze and frontal lobe release signs eventually became apparent in half of the patients.

Postmortem examination of several of our colleagues’ patients, reported by Rebeiz and colleagues, has disclosed a combination of findings that stamps the disease process as unique. Cortical atrophy (mainly in the frontal motor-premotor and anterior parietal lobes) was associated with degeneration of the substantia nigra and, in one instance, of the dentatorubrothalamic fibers. The loss of nerve cells was fairly marked, but there was no gross lobar atrophy, as occurs in Pick disease. The neuronal degeneration was more on one side of the brain than the other. There was moderate gliosis in the cortex and underlying white matter. Many of the residual nerve cells were swollen and chromatolyzed with eccentric nuclei, a state that was called achromasia by Rebeiz and colleagues; it resembled the central chromatolysis of axonal reaction. More recently, in over half the cases, the affected neurons and adjacent glia have been shown to be filled with a particular configuration of tau protein, thereby linking the disease to frontotemporal dementia and Pick disease, as already mentioned. The remaining cases have shown tau deposition that is more similar to that of progressive supranuclear palsy, or Alzheimer pathology, or non-specific cell loss with replacement gliosis.

Both CT and MRI have demonstrated asymmetrical cerebral and pontine atrophy, and PET studies have revealed thalamoperi-tetal metabolic asymmetries—a greater reduction of glucose metabolism on the side of the most extensive lesion (Riley et al).

In subsequent observations of such cases, other investigators have searched unsuccessfully for clues as to the cause and pathogenesis of this disease. There is no family history. No organ other than the CNS is affected. The progression is relentless. None of the drugs in common use for spasticity, rigidity, and tremor has been helpful. We know of no attempt to transfer the disease to primates.

Marinescu has described a somewhat different disease resembling more a severe form of Alzheimer disease, but with signs of both pyramidal and extrapyramidal disease (rigidity, tremor, nystagmus, incoordination, confusion, disorientation, and loss of memory). There was amyloidosis of blood vessels (so-called Scholz’s perivascular plaques) in the cerebral white matter as well as in the liver and kidney. The disease bears some resemblance to, and may indeed be identical to, the corticostriatospinal degeneration (“spastic pseudosclerosis”) of Jakob, discussed on page 913. The relation of this disease to the corticopallidospinal and the pallidopy-
ramidal syndromes first described by Davison (1932, 1954) is also uncertain. The features of eight such cases of a “pallidopramidal” syndrome have more recently been summarized by Tranchant and associates.

**Dystonia Disorders**

**Dystonia Musculorum Deformans (Torsion Dystonia)** Dystonia as a symptom has been discussed in Chaps. 4 and 6. Here we are concerned with a disease or diseases of which dystonia is the major manifestation. Schwabé’s account, in 1908, of three siblings of a Jewish family who were afflicted with progressive involuntary movements of trunk and limbs probably represents the first description of a disease in which severe and progressive dystonia was the sole manifestation. In 1911, Oppenheim contributed other cases and coined the term *dystonia musculorum deformans* in the mistaken belief that the disorder was primarily one of muscle and always associated with deformity. Flatau and Sterling, in the same year, first suggested that the disease might have a hereditary basis and gave it the more accurate name *torsion dystonia of childhood*. At first the condition was thought to be a manifestation of hysteria, and only later was it recognized as a neurologic entity with a predilection for Russian and Polish Jews. Soon thereafter, a second hereditary form of torsion dystonia, affecting non-Jews, was observed. The epidemiologic study of Eldridge, who analyzed all reported primary cases up to 1970, revealed two patterns of inheritance, one autosomal recessive, the other dominant. The recessive form begins in early childhood, is progressive over a few years, and is restricted to Jewish patients with normal and often even superior intelligence. The dominant form begins later, usually in late childhood and adolescence, progresses more slowly, and is not limited to any ethnic group.

As indicated in Chap. 6, most instances of idiopathic (primary) dystonias that come to our attention, particularly the segmental or restricted types, do not conform to the classic hereditary disorders as defined above, although some may represent limited variants. In general, these more restricted types have a later onset and a relatively milder, more slowly progressive course, with a tendency to involve the axial or the distal musculature alone. Only the para-vertebral, cervical, or cranial muscles may be involved (focal dystonia including torticollis and writer’s cramp), with little change from year to year. The clinical classification of the predominantly adult-onset dystonias is made more complex by the fact that both the restricted and generalized forms may be sporadic or familial. Bressman and colleagues, for example, have described a restricted (cervicocranial) adult-onset form of dystonia in four generations of a non-Jewish family. The symptomatology included cervical dystonia, facial grimacing, dystarthis, and dysphonia. In one of our familial cases, a dystonia of the foot appeared during adolescence and later disappeared; we have also observed this time-limited occurrence to happen occasionally in spasmotic torticollis, which is a common form of restricted or segmental dystonia, described further on.

In a survey of idiopathic torsion dystonia of local and generalized type in the United Kingdom by Fletcher and associates, the investigators concluded that approximately 85 percent of these cases were due to an autosomal dominant gene of low penetrance and that a small proportion represented new mutations. The risk of the disease in a first-degree relative of a familial case is about 25 percent.

Molecular genetic studies, though still incomplete, hold the promise of clarifying the classification of the heritable dystonias (see Korf). More than 10 types of dystonia have been distinguished by genetic mapping. The most important of these is an abnormal gene (DYT1), which codes for the protein torsin A, that has been mapped to the long arm of chromosome 9q in both Jewish and non-Jewish families. The most common DYT1 mutation, deletion of a single glutamate from the torsin A peptide, is found in most cases of dystonia musculorum deformans, as discussed in Chap. 4. This disease is inherited in an autosomal dominant pattern. Although the penetrance of the clinical trait in these families is low, PET scanning demonstrates hypermetabolism in the cerebellum, lenticular nuclei, and supplementary motor cortex in all carriers of the mutated gene.

The function of torsin A is not fully defined. It is present in neurons throughout the brain and has ATP binding and nuclear localization. It may function as a chaperone protein that shuttles other proteins in and out of cells. A current speculation, shared with other degenerative disease, is that the absence of torsin A renders neurons unduly sensitive to oxidative stress (Walker and Shashidharan).

German Mennonite families with restricted adult-onset dystonia (torticollis and spasmodic dysphonia) have an unrelated mutation at 18p; a rare X-chromosome mutation that causes dystonia has also been described. Another rare form of dystonia with myoclonus is caused by mutations in the gene encoding e-sarcoglycan, a transmembrane protein. A unique, dopa-sensitive dystonia, described below, arises from a dominantly transmitted defect on chromosome 14q in the protein GTP cyclohydrolase (see below, under “Hereditary Dystonia-Parkinsonism”).

Although DYT1 mutations account for the majority of inherited cases of generalized dystonia, they are implicated in a relatively small proportion of the more restricted dystonias (see further on). Perhaps it is more notable that some cases of apparently sporadic and regionally restricted dystonias are indeed associated with the mutation or variants of it. However, the relationship of these inherited childhood and adolescent varieties of generalized dystonia to the more common sporadic and restricted dystonias has not been settled. It is true that some individuals in families affected with generalized dystonia will demonstrate only localized forms (e.g., writer’s cramp or torticollis). The general rule stated above still holds—namely, that the inherited variety (dystonia musculorum deformans) related to chromosome 9q manifests early in life and begins in one limb, then spreads to most muscles of the body, while in the common dystonias (mostly sporadic but some of which may be heritable) the disease remains confined to the craniocervical or another region and does not generalize or progress.

**Clinical Features** The first manifestations of the generalized disease may be rather subtle. Intermittently, and usually after activity (late in the day), the patient (usually a child between 6 and 14 years of age, less often an adolescent) begins to invert one foot, to extend one leg and foot in an unnatural way, or to hunch one shoulder, raising the question of a nervous tic. As time passes, however, the motor peculiarity becomes more persistent and interferes increasingly with the patient’s activities. Soon the muscles of the spine and shoulder or pelvic girdles become implicated in involuntary, spasmotic twisting movements. The cardinal feature of these severe dystonic muscle contractions is the simultaneous contraction of both agonists and antagonists at a joint. These cocontraction spasms are intermittent at first; in free intervals, muscular tone and volitional movements are normal. Indeed, in some instances the
muscules are hypotonic. Gradually the spasms become more frequent; finally they are continuous, and the body may become grotesquely contorted. Lateral and rotatory scoliosis are regular secondary deformities. For a time, recumbency relieves the spasms, but later on position has no influence. The hands are seldom involved, though at times they may be fisted. Cranial muscles do not escape, and in a few instances a slurring, staccato-type speech has even been the initial manifestation. Uncontrollable blepharospasm was the initial disorder in one of our patients; in two others, severe dysarthria and dysphagia were the first signs of the disease, caused by dystonia of the tongue, pharyngeal, and laryngeal muscles. Other manifestations of the movement disorder include torticollis, tortipelvis, dromedary gait, propulsive gait, action tremor, myoclonic jerks during voluntary movement, and mild choreoathetosis of the limbs. Excitement worsens the condition and sleep abolishes it. As the years pass the postural distortion may become fixed to the point where it does not disappear even in sleep. Tendon reflexes are at all times normal; corticospinal signs are absent; there is no ataxia, sensory abnormality, convulsive disorder, or dementia.

**Pathology** No agreement has been reached concerning the pathologic substrate of the disease. In several cases the ferrocalcinosis of Hallervorden-Spatz disease, the lesions of Wilson disease or of kernicterus, the état marbré of neonatal hypoxia, or the CT lesions of familial striatal necrosis have been observed in the basal ganglia. Obviously in these instances the dystonia was symptomatic of another disease. However, in the hereditary forms, which are the subject of this section, one cannot be certain of any specific lesions that would account for the clinical manifestations. The brain is grossly normal, and the ventricular size is not increased. According to Zeman, who reviewed all the reported autopsy studies up to 1970, there are no significant changes in the striatum, pallidum, or elsewhere. This does not mean that there are no lesions, only that the techniques being used (qualitative analysis of random sections by light microscopy) are inadequate for their demonstration or the problem is subcellular. The recent report by McNaught and colleagues of perinuclear inclusions in periaqueductal neurons by the use of special immunostaining methods is provocative. It is worth remarking that in more contemporary studies, abnormalities of torsin A protein has not been detected in autopsy tissue from individuals with either dystonia muscularum deformans or other forms of dystonia. Newer methods of identification of striatal cell types and quantification of protein levels have probably not been adequately evaluated. Dopamine β-hydroxylase is elevated in the plasma of patients with the autosomal dominant form of the disease and the plasma norepinephrine levels are also raised, but the meaning of these findings is not clear; PET scan changes have already been mentioned.

**Treatment** Early in the course of the illness, several drugs—including L-dopa, bromocriptine, carbamazepine, diazepam, and tetrazenemazine—seem to be helpful, but only in a few patients, and the benefit is not lasting. Intrathecal baclofen has been somewhat more successful in children. The rare hereditary form of dystonia-parkinsonism (described below) responds well to small doses of L-dopa and dopamine agonists and is exceptional in this respect. Burke and coworkers advocate the use of very high doses (up to 30 mg daily or more) of trihexyphenidyl (Artane). Apparently dystonic children can tolerate these high doses if the medication is raised gradually, by 5-mg increments weekly. In adults, high-dose anticholinergic treatment is less successful but worthy of a trial. Clonazepam is beneficial in some patients with segmental myoclonus.

The most impressive results have been obtained by the use of stereotactic techniques to make lesions that are centered in the ventrolateral nuclei of the thalamus or in the pallidum–ansa lenticularis region. Some frightfully deformed children, unable to sit or stand, have been restored to near normalcy for a time. Approximately 70 percent of the patients in Cooper’s series were moderately to markedly improved by unilateral or bilateral operations, and, based on a 20-year follow-up study, the improvement was usually sustained. More recent studies have reported a somewhat less favorable but nonetheless clear-cut improvement (see Tasker et al; Andrew et al). The main risk of operation has been a corticospinal tract lesion, produced inadvertently by damaging the internal capsule. Bilateral lesions have sometimes been disastrous, causing pseudobulbar palsy. Newer techniques employing stimulators and implanted electrodes may give better results.

**Hereditary Dystonia-Parkinsonism (Segawa Syndrome, Juvenile Dopa-Responsive Dystonia)** This process is discussed here because its main characteristic is a dystonia that is responsive to L-dopa, but most cases also have features of parkinsonism; it is therefore included in the differential diagnosis of that syndrome in young patients. Following the description of this disease by Segawa and colleagues in 1976, several others drew attention to a unique form of hereditary dystonia (Allen and Knopp; Deonna; Nygaard and Duvoisin). The pattern of inheritance is probably autosomal dominant and there is no ethnic predilection. Nygaard and colleagues have found a linkage to the gene on chromosome 14q for a protein GTP cyclohydrolase 1. This gene is implicated in the synthesis of tetrahydrobipterin, which is a cofactor for tyrosine hydroxylase. It is likely that mutation impairs the generation of dopamine, a prediction that accords with responsiveness of the parkinsonian and dystonic features to L-dopa. In one autopsied case (an accidental death), there was a reduction in the amount of tyrosine hydroxylase in the striatum and depigmentation but no cell loss in the substantia nigra (Rajput et al). The affected enzyme was reduced in the striatum, as was the level of dopamine.

The dystonic manifestations usually become evident in childhood, usually between 4 and 8 years of age; females outnumber males in a ratio of 3 to 2. Often the legs are first affected by intermittent stiffening, with frequent falls and peculiar posturing, sometimes the feet assuming an equinovarus position. The arms become involved as well as the truncal muscles; retrocollis or torticollis may appear. Within 4 to 5 years, all parts of the body including the bulbar muscles are involved. Sometimes, as mentioned, parkinsonian features (rigidity, bradykinesia, postural instability) can be detected early in the course of the illness, but characteristically they are added to the clinical picture several years later. In our own patients and in several of those of Deonna, there was in some instances a rigidity of the limbs as well as slowness of movement and a tremor at rest, all aspects more parkinsonian than dystonic. In still others, the clinical picture has been one of cerebral spastic diplegia.

A remarkable feature is the disappearance or marked subsidence of the symptoms after a period of sleep and worsening as the day progresses. This diurnal variation has been a notable feature in some but not all cases and is shared with many of the inherited forms of Parkinson disease discussed earlier. Fluctuations of symptoms with exercise and menses and in the first month of pregnancy have been observed in some cases.

The unique feature of this juvenile dystonia-parkinsonism syndrome, as it has also been called, is the dramatic response of both
the dystonic and parkinsonian symptoms to treatment with L-dopa. As little as 10 mg/kg per day may eliminate the movement disorder and permit normal functioning. In this condition, unlike Parkinson disease, the medication can be continued indefinitely without the development of tolerance or wearing-off effects. Segawa disease accounts for some cases that had in the past been reported as juvenile Parkinson disease.

**Torticollis and Other Restricted Dyskinesias and Dystonias** (See Chap. 6) With advancing age, a large variety of degenerative movement disorders come to light. Supposedly there is loss of neurons in certain parts of the basal ganglia, but this has not been verified by appropriate pathologic studies. In the common restricted dystonias, localized groups of adjacent muscles manifest arrhythmic cocontracting spasms (agonist and antagonist muscles are activated simultaneously). The patient’s inability to suppress the dystonia and the recognition that it is for the most part beyond voluntary control distinguishes it from typical tics, habit spasms, and mannerisms described in Chap. 6. If the muscle contraction is frequent and prolonged, it is accompanied by an aching pain that may mistakenly be blamed for the spasm, and the involved muscles may gradually undergo hypertrophy. Worsening under conditions of excitement and stress and improvement during quiet and relaxation are typical of this group of disorders and contributed in the past to the mistaken notion that the spasms had a psychogenic origin.

The most frequent and familiar type is *torticollis* as described in Chap. 6, wherein an adult, more often a woman, becomes aware of a turning of the head to one side while walking. Usually this condition worsens gradually to a point where it may be more or less continuous, but in some patients it remains mild or intermittent for years on end. When followed over the years, the condition is observed to remain limited to the same muscles (mainly the scalene, sternocleidomastoid, and upper trapezius). Rarely the torticollis is combined with dystonia of the shoulder, arm and trunk; tremor; facial spasms; or dystonic writer’s cramp.

Other restricted dyskinesias involve the neck in combination with facial muscles, the orbicularis oculi (*blepharospasm* and *blepharoclonus*), the throat and respiratory muscles (“*spastic phonia,*” *orofacial dyskinesia,* and *respiratory and phonatory spasms*), the hand in writer’s cramp (*graphospasm*) or musician’s dystonia, and proximal leg and pelvic-girdle muscles, where dyskinesia is elicited by walking. All these conditions and their treatment are discussed fully in Chap. 6.

**Other Forms of Hereditary Dystonia** Several familial movement-induced (kinesogenic) dystonic syndromes and a type that is not kinesogenic and arises suddenly in adolescence, at times with parkinsonian features, have been described (see page 184). There are other degenerative diseases that combine hereditary dystonia with neural deafness and intellectual impairment (Scribanu and Kennedy) and with myotrophy in a paraplegic distribution (Gilman and Romanul).

Two other important diseases that fall into the category of hereditary dystonia have been described in Chap. 37. These are Hallervorden-Spatz disease and calcification of the basal ganglia—and, of course, Wilson disease may have dystonia as a central feature. Also, many extrapyramidal diseases, including idiopathic Parkinson disease and progressive supranuclear palsy, may include fragmentary dystonias of the hand, foot, face, or periorbital muscles.

### Syndrome of Progressive Ataxia

This topic was introduced in Chap. 5, and some of the congenital and acute acquired varieties are mentioned on pages 818, 826, and 976. Here we consider only the chronic, progressive forms of cerebellar disease. While many of these are familial and are more or less confined to this part of the nervous system, a number of other systems may be involved to a varying degree. Many of these diseases are so chronic that one would expect a close correspondence between their symptomatology and anatomic pathology, yet attempts to determine these relationships have generally been disappointing. The classic examples of chronic progressive cerebellar disease are subsumed under the “system atrophies,” but no one classification designed to bring precise order to this category of diseases has proved entirely satisfactory. Wilson wrote that “the group of degenerative conditions strung together by the common feature of ataxia is one for which no very suitable classification has yet been devised”—a statement that is as appropriate today as when it was written about 70 years ago. Even recent insights provided by the tools of molecular genetics have not provided a satisfactory basis for classification, mainly because the same gene abnormality may be expressed by a number of different phenotypic syndromes.

Nevertheless, largely through the clinical and pathologic studies of Greenfield and subsequent reviews by Harding and others, a semblance of order has been achieved. The clinical classification proposed by Harding represents a scholarly effort to meet this goal. Setting aside those of congenital type and those caused by an underlying metabolic disorder, she grouped the ataxias by age of onset, pattern of heredity, and associated features. A modification of the classifications of Greenfield and of Harding, which is included in the introductory listing of the degenerative diseases (page 897) is used here. It divides the progressive cerebellar ataxias into three groups—(1) the spinocerebellar ataxias, with unmistakable involvement of the spinal cord (Romberg sign, sensory loss, diminished tendon reflexes, Babinski signs); (2) the pure cerebellar ataxias, with no other associated neurologic disorders; and (3) the complicated cerebellar ataxias, with a variety of retinal, optic nerve, oculomotor, auditory, pyramidal, extrapyramidal, peripheral nerve, and cerebrocortical accompaniments. Inherited ataxias of early onset (before the age of 20 years) are usually of autosomal recessive type; those of later onset may be autosomal recessive but are more likely autosomal dominant. Table 39-5 provides a listing of several types of ataxia that have a genetic basis. At the same time, it should be emphasized that many patients in our clinics have no family history of a similar ataxia.

In the approach to a patient with a heritable ataxia, we find such a classification—based on well-established clinical and pathologic features and patterns of mendelian inheritance—to be the most useful. Without doubt, the advances in molecular genetics of recent years have greatly altered our understanding of the inherited ataxias and has already disclosed a large number of unexpected relationships between specific genetic defects and other neural and nonneural disorders. These data are incorporated at appropriate points in the following discussion and are summarized in Table 39-5 and at the end of this section.

#### Early-Onset Spinocerebellar Ataxias (Predominantly Spinal)

**Friedreich Ataxia** This is the prototype of all forms of progressive spinocerebellar ataxia and accounts for about half of all cases

* CAG expansion.
of hereditary ataxia in most large series (86 of 171 cases in Sjögren's series); its incidence among Europeans and North Americans is 1.5 per 100,000 cases per year. Friedreich, of Heidelberg, began in 1861 to report on a form of familial progressive ataxia that he had observed among nearby villagers. It was already known through the writings of Duchenne in Paris that locomotor ataxia was the prominent feature of spinal cord atrophy, i.e., tabes dorsalis, but it was Friedreich who demonstrated that a nonspinalritic hereditary type also existed. This concept was greeted with some skepticism, but soon Duchenne himself affirmed the existence of the new disease and other case reports appeared in England, France, and the United States. In 1882, in a thesis on this subject by Brousse of Montpelier, Friedreich's name was attached to the new entity.

As further cases appeared, it was noted that in about half the onset was before the tenth year and sometimes as early as the second or third year; Mollaret could find no examples with onset after the age of 25 years. The disease is always steadily progressive; within 5 years of onset, walking is no longer possible in many cases. Genetic linkage studies of 22 families with three or more affected siblings have led to the assignment of the gene mutation to chromosome 9q13-2 (Chamberlain et al.). Subsequently, a form of Friedreich ataxia of later onset (between 20 and 30 years) and slower progression has been recorded (De Michele et al.); in this form, the gene abnormality, like that of the classic Friedreich ataxia, is in the centromeric region of chromosome 9. In the vast majority of cases the chromosome 9 mutation is an expansion of a GAA trinucleotide repeat within a gene that codes for the protein frataxin. (It is of interest that this mutation is within an intron). In a very small proportion of cases, the mutation is a missense mutation rather than an expansion. In either case, the consequence of the mutation is a reduction in levels of frataxin and loss of its function. This is consonant with the recessive pattern of inheritance. Cases in which the mutation allows the presence of some residual protein have a milder course. A current hypothesis is that frataxin is a mitochondrial matrix protein whose function is to prevent intramitochondrial iron overloading.

**Clinical Features**  
Ataxia of gait is nearly always the initial symptom. Occasionally the ataxia begins rather abruptly after a febrile illness, and one leg may become clumsy before the other. This “hemiplegic” pattern is exceptional; usually both legs are affected simultaneously. Difficulty in standing steadily and in running are early symptoms; however, Wilson had commented on fatigability, leg pains, and postexertional cramps—symptoms that we have seldom elicited. The hands usually become clumsy months or years after the gait disorder, and dystarthric speech appears after the arms are involved (this is rarely an early symptom).

In some patients, pes cavus and kyphoscoliosis precede the neurologic symptoms; in others, they follow by several years. The characteristic foot deformity takes the form of a high plantar arch and retraction of the toes at the metatarsophalangeal joints and flexion at the interphalangeal joints (hammertoes).

A notable feature is cardiomyopathy, which is demonstrable in more than half the patients. The myocardial fibers are hypertrophic and may contain iron-reactive granules (see Koeppen). Many of the patients die as a result of cardiac arrhythmia or congestive heart failure. For this reason, it is essential that affected individuals have a cardiologic assessment including regular electrocardiography and echocardiography. The cardiomyopathy of Friedreich disease can develop insidiously but with fulminating consequences, for which reason cardiologists caring for these patients should be knowledgeable about the neurologic disease. Kyphoscoliosis and restricted respiratory function are also important contributory causes of death. Harding observed that about 10 percent of these patients have diabetes mellitus and a similar proportion have impaired glucose tolerance.

In the fully developed state, the abnormality of gait is of mixed sensory and cerebellar type, aptly called tabetocerebellar by Charcot. According to Mollaret, the author of an authoritative monograph on the disease, the cerebellar component predominates, but in our relatively small series we have been impressed almost as much with the sensory (tabetic) aspect. The patient stands with feet wide apart, constantly shifting position to maintain balance. Friedreich referred to the constant teetering and swaying on standing as static ataxia. In walking, as with all sensory ataxias, the movements of the legs tend to be brusque, the feet resounding unevenly and irregularly as they strike the floor, and closure of the eyes causes the patient to fall (Romberg sign). This reflects the spinal component (posterior columns). Attempts to correct the imbalance may result in abrupt, wild movements. Often there is a rhythmic tremor of the head. The arms are grossly atatic, and both action and intention tremors are manifest. Speech is slow, slurred, explosive, and finally almost incomprehensible. Breathing, speaking, swallowing, and laughing may be so incoordinated that the patient nearly choke while speaking. Holmes remarked on an ataxia of respiration that causes “curious short inspiratory whoops.” Facial, buccal, and arm muscles may display tremulousness and sometimes choreiform movements. Mentation has been preserved in all our patients. However, emotional lability has been sufficiently prominent to provoke comment by others. Horizontal nystagmus may be present with the eyes in the primary position and is increased on lateral gaze. Rotatory and vertical nystagmus are rare. Deafness has been recorded, along with vertigo and, more rarely, with inexcitability of the labyrinth and blindness with optic atrophy. Ocular movements usually remain full, and pupillary reflexes are normal. The facial muscles may seem slightly weak, and deglutition may become impaired. Amyotrophy occurs late in the illness and is usually slight, but it may be extreme in patients with an associated neuropathy (see below). The tendon reflexes are abolished in nearly every case; rarely, they may be obtainable when the patient is examined early in the illness (see below). Plantar reflexes are extensor, and flexor spasms may occur even with complete absence of tendon reflexes, indicating that the areflexia is sensory in origin. The abdominal reflexes are usually retained until late in the illness. Loss of vibratory and position sense is invariably from the beginning; later, there may be some diminution of tactile, pain, and temperature sensation as well. Sphincter control is usually preserved.

In one important variant of Friedreich ataxia the tendon reflexes are preserved or even hyperactive and the limbs may be spastic. Some of these cases are associated with hypogonadism. It is the finding of the aberrant frataxin gene on chromosome 9 that links these cases to Friedreich ataxia. Harding found 20 such cases among her 200 familial ataxias at the National Hospital, London. Nevertheless, the distinction between classic Friedreich ataxia and ataxia with retained tendon reflexes is an important one clinically, insofar as kyphoscoliosis and heart disease do not occur in the latter group and the prognosis is better. In other cases, some familial, a spastic paraparesis and optic atrophy are combined with ataxia (Behr). We would also include here cases of the type described by Hogan and Bauman, in which a progressive cerebellar ataxia was associated with spasticity and other corticospinal tract signs of the legs. Cerebellar atrophy has not been a prominent feature of these cases, and we would adopt the position that they are forms of spi-
nocerebellar degeneration that are transitional between Friedreich ataxia and some of the other heredoataxias with cerebellar atrophy. In the few autopsied cases, the main abnormality has been in the spinal cord and the spinocerebellar (cerebellulopetal) tracts, but some in addition show corticospinal tract degeneration.

Other abortive and atypical forms are numerous. Peroneal muscular atrophy is sometimes associated with Friedreich ataxia, as is true of the areflexic dystasia (sensory neuropathy) of Roussy and Levy. These disorders are discussed with the hereditary neuroopathies on page 1157. Hereditary forms of optic atrophy, retinitis pigmentosa, deafness, and myoclonus are occasionally combined with Friedreich ataxia as well, but we agree with Skre that they probably represent genetically independent entities. Two of our Friedreich patients had occasional seizures.

Laboratory tests of diagnostic value are the measurement of sensory nerve conduction velocities and amplitudes, electrocardiography (demonstrating signs of ventricular hypertrophy and in some, heart block), and chest and spine films (to show heart size and kyphoscoliosis). The CT scans and MRI seldom reveal a significant degree of cerebellar atrophy; the spinal cord is small. There is no consistent abnormality of blood or CSF. Visual evoked potentials are abnormal only in patients with associated optic atrophy.

Pathology The spinal cord is thin. The posterior columns and the corticospinal and spinocerebellar tracts are all depleted of medullated fibers, and there is a fibrous gliosis that does not replace the bulk of the lost fibers. The nerve cells in Clarke’s column and the large neurons of the dorsal root ganglia, especially lumbosacral ones, are reduced in number—but perhaps not to a degree that would fully explain the posterior column degeneration. The posterior roots are thin. Betz cells are also diminished in some cases, but the corticospinal tracts are relatively intact down to the medullary-cervical junction. Beyond this point, they are degenerated, but to a lesser degree than the posterior columns. The nuclei of cranial nerves VIII, X, and XII all exhibit a reduction of cells.

Slight to moderate neuronal loss is seen also in the dentate nuclei, and the middle and superior cerebellar peduncles are reduced in size. Some depletion of Purkinje cells in the superior vermis and neurons in corresponding parts of the inferior olivary nuclei can be seen.

Many of the myocardial muscle fibers degenerate and are replaced by fibrous connective tissue. No consistent biochemical abnormalities have been demonstrated.

By way of exploring the anatomic basis of the clinical findings, pes cavus is not different from that seen in other diseases with mild hypertonus of the long extensors and flexors of the feet and in the early-onset hereditary polyneuropathies. These also cause amytrophy of intrinsic foot muscles when the bones of the feet are still malleable. The kyphoscoliosis is probably due to imbalance of the paravertebral muscles. The tabetic aspects of the disease are explained by the degeneration of large cells in the dorsal root ganglia and the large sensory fibers in nerves, dorsal roots, and the columns of Goll and Burdach. The loss of large neurons in the sensory ganglia also causes abolition of tendon reflexes. The cerebellar ataxia is attributable to a degeneration of the spinocerebellar tracts, the superior vermis, and the dentatorubral pathways in various combinations. Corticospinal lesions account for the weakness and Babinski signs and contribute to the pes cavus as well.

Diagnosis Friedreich disease and its variants must be distinguished from familial cerebellar cortical atrophy, described next, and from familial spastic paraparesis with ataxia, as well as from peroneal muscular atrophy and the Levy-Roussy syndrome, which are discussed with the hereditary neuropathies in Chap. 46. It is advisable to assay serum vitamin E levels, since a rare but treatable inherited deficiency of a vitamin E transport protein causes a spinocerebellar syndrome with areflexia in children, resembling Friedreich’s disease, as detailed in Chap. 41. This vitamin deficiency syndrome is difficult to distinguish from Friedreich ataxia, but the absence of dysarthria and of skeletal or cardiac abnormalities may be helpful. Exceptionally, a cardiac disturbance has been seen. A form of chronic inflammatory demyelinating polyneuropathy has long since overtaken tabes dorsalis as the most frequent type of areflexic ataxia. It bears a superficial resemblance to Friedreich ataxia when the onset is in childhood but lacks dysarthria and Babinski signs. A form of spinocerebellar degeneration related to human T-cell lymphotropic virus type I (HTLV-I), causing so-called tropical spastic paraparesis as well as the vacuolar myelopathy of AIDS, must also be included in the differential diagnosis of late-onset cases.

Treatment Not much can be said on this subject since there is little effective therapy. A double-blind crossover study by Trouillas and associates found that the administration of oral 5-hydroxytryptophan modified the cerebellar symptoms. This drug is serotoninergic and is known to suppress posthypoxic action myoclonus. Apart from this form of treatment, with which we have had no experience, no therapeutic measures are known to alter the course of the neurologic disease. Idebenone, an antioxidant (the short-chain analogue of coenzyme Q10) has been shown in several small trials to reduce the progression of left ventricular hypertrophy, a substantial risk factor for arrhythmias and sudden death in these patients, but it does not affect the ataxia. These results are summarized in an article by Filla and Moss. Heart failure, arrhythmias, and diabetes mellitus are treated by the usual medical measures. Surgery for scoliosis and foot deformities may be helpful in selected cases.

Predominantly Cerebellar (Cortical, Holmes Type) Forms of Hereditary and Sporadic Ataxia

Soon after the publication of Friedreich’s descriptions of a spinal type of hereditary ataxia, reports began to appear of somewhat different diseases in which the ataxia was related to degenerative changes in the cerebellum and brainstem rather than the spinal cord. Claims of their independence from the spinal type were based largely on a later age of onset, a more definite hereditary transmission (usually of autosomal dominant type), the persistence or hyperactivity of tendon reflexes, and the more frequent concurrence of ophthalmoplegia, retinal degeneration, and optic atrophy. Several of these clinical features, particularly briskness of tendon reflexes, are alien to the classic form of Friedreich ataxia.

By 1893 Pierre Marie thought it desirable to create a new category of hereditary ataxia that would embrace all of the non-Friedreich cases. He collated the familial cases of progressive ataxia that had been described by Fraser, Nonne, Sanger Brown, and Klippel and Durante (see Greenfield and Harding for references) and proposed that all of them were examples of an entity to which he applied the name hérédoo-ataxie cérébelleuse. Marie’s proposition was based almost entirely on clinical observations—not his own but those made by the aforementioned authors. Later, as members of these families died, postmortem examinations disclosed that Marie’s hereditary cerebellar ataxia included not one but several disease entities. Indeed, as pointed out by Holmes
(1907) and later by Greenfield, in three of the four families the cerebellum showed no significant lesions at all. Yet there was by then no doubt of the existence of a separate class of predominantly cerebellar atrophies, some purely cortical and others associated with a variety of noncerebellar lesions.

**Clinical Features** Holmes in 1907 described a family of eight siblings, of whom three brothers and one sister were affected by a progressive ataxia, beginning with a reeling gait and followed by clumsiness of the hands, dysarthria, tremor of the head, and a variable nystagmus. It may be taken as the prototype of pure cerebellar cortical degeneration. The ataxia began insidiously in the fourth decade and progressed slowly over many years. The late cortical cerebellar atrophy of Marie, Foix, and Alajouanine, reported in 1922, is probably the same disease. In their patients also, the onset was in later life (average age 57 years). The onset was usually insidious, rarely abrupt, and the progress was extremely slow, allowing survival for 15 to 20 years. Ataxia of gait, instability of the trunk, tremor of the hands and head, and slightly slowed, hesitant speech conformed to the usual clinical picture of a progressive cerebellar ataxia. Nystagmus was rare. Intelligence was usually preserved. The patellar reflexes were increased in many cases, the ankle jerks were often absent, and the plantar reflexes were said to be extensor in some. The last finding, in the absence of hyperreflexia and spasticity, must be accepted with caution, since avoidance-withdrawal responses are often mistaken for Babinski signs. In our own practices, sporadic forms of pure cerebellar degeneration have been as common as inherited ones, as already mentioned, but we have not performed extensive genetic testing. The differential diagnosis in the nonfamilial cases is quite broad, as discussed at the end of this section.

**Pathology** Postmortem examination of the Holmes-type cases disclosed a symmetrical atrophy of the cerebellum involving mainly the anterior lobe and vermis, the latter being more affected than the hemispheres. The Purkinje cells were absent in the lingula, centralis, and pyramids of the superior vermis and reduced in number in the quadrigeminal, flocculus, biventral, and pyramidal lobes. The other cerebellar cortical neurons and granule cells were diminished in number, but the latter less so. The white matter was slightly pale in myelin stains. The roof and pontine nuclei were normal. There was cell loss in the dorsal and medial parts of the inferior olivary nuclei. A questionable pallor was noted in the corticospinal and spinocerebellar tracts in myelin stains of the spinal cord. The vermian atrophy and that of adjacent parts of the cerebellum can be visualized with great clarity in MRIs (Fig. 39-7).

The pathologic findings in the cases of Marie, Foix, and Alajouanine were essentially the same. In further reports, both familial and sporadic cases of this type have been collected. The similarity of the pathologic (and clinical) changes to those of *atrophic* cerebellar degeneration is at once apparent and should always raise the question of an alcoholic-nutritional cause in sporadic cases (Chap. 41).

**Cerebellar Atrophy with Prominent Brainstem Features (Sporadic and Familial Olivopontocerebellar Atrophy)**

A sporadically occurring instance of a disorder closely resembling the Holmes type of cortical cerebellar degeneration but with additional features of brainstem atrophy was described in 1900 by Déjerine and André-Thomas, who named it *olivopontocerebellar atrophy* (OPCA). The onset of symptoms was in the fifth decade of life, and the main manifestations were ataxia—first in the legs, then in the arms, hands, and bulbar musculature—a symptomatology common to all the cerebellar atrophies. As more and more cases of this type were collected (by 1943, Rosenhagen had collected 45 from the literature, to which he added 11 of his own), a hereditary pattern (autosomal dominant) was evident in some, and one or more long tracts in the spinal cord were found to have degenerated. About half the cases later developed the symptoms of Parkinson disease with degeneration of nigral cells and, in a few, of striatal cells as well, thereby linking the disease to striatonigral degeneration and what is now called *multiple system atrophy* (MSA) (see earlier discussion of this entity and below).

Notable findings in both the sporadic (Menzel and Déjerine-Thomas types) and the familial forms of OPCA are the extensive degeneration of the middle cerebellar peduncles, the cerebellar white matter, and the pontine, olivary, and arcuate nuclei; loss of Purkinje cells has been variable. Most likely this degeneration represents a terminal “dying back” of axons of the pontine and olivary nuclei with secondary myelin degeneration. The extreme atrophy of the medullary olivary nuclei virtually identifies the process and is evident on MRIs (Fig. 39-8).

In addition to the linkage in some cases with striatonigral degeneration, the boundaries of the entity of hereditary OPCA have gradually been extended; Königsmark and Weiner subdivided them into the following types: (1) hereditary (dominant) type of Menzel; (2) hereditary (recessive) type of Fickler-Winkler; (3) hereditary (dominant) type with retinal degeneration; (4) hereditary (dominant) type of Shut-Haymaker, with spastic paraplegia and areflexia; and (5) hereditary (dominant) type with dementia, ophthalmoplegia, and extrapyramidal signs. But even this classification does not do justice to the variable presentations. To these can be added two additional types: (6) inherited cases of OPCA with neuropathy and slowed eye movements described by Wadia, of which we have seen two cases, and (7) cases with dystonia and a variety of other clinical findings, most of them in single cases or single families (hemiballismus, athetosis, contractures of the legs, fixed pupils, ophthalmoplegia, ptosis, gaze palsy, deafness, retinal degeneration, mental

![Figure 39-7. Familial cortical cerebellar atrophy. T1-weighted MRI in the sagittal plane showing marked atrophy of vermis and enlargement of fourth ventricle. The brainstem is only mildly atrophic. Compare with Fig. 39-8 in which the cerebellum andpons are atrophic.](image-url)
have seen, the extrapyramidal symptoms were mainly rigidity and was no impairment of intellect, and in the examples the authors bulbar signs, distal motor weakness, and ophthalmoplegia. There hyperreflexia, extrapyramidal (parkinsonian) rigidity, dystonia, beginning in adolescence or early adult life in association with dominant pattern of inheritance and by a slowly progressive ataxia.

...the cause of otherwise undifferentiated sporadic ataxia is given in long arrow.

...The extrapyramidal and neuropathic signs, slow eye movements, dysarthria, nystagmus, slowness of eye movements, reduced facial mobility, slow lingual movements, fasciculations of face and tongue, dystonic postures, rigidity of the limbs, cerebellar tremor, hyperreflexia, and Babinski signs.

A similarly affected Azorean family named Joseph was de scribed by Rosenberg and colleagues (1976) under the name of autosomal dominant striatonigral degeneration. The disease had its onset in early adult life and was characterized by progressive ataxia of gait, followed by dysarthria, nystagmus, slowness of eye movements, reduced facial mobility, slow lingual movements, fasciculations of face and tongue, dystonic postures, rigidity of the limbs, cerebellar tremor, hyperreflexia, and Babinski signs.

Under the name Azorean disease of the nervous system (now better known as Machado-Joseph disease), Romanul and colleagues described yet another family of Portuguese-Azorean descent, many members of which were affected by a syndrome comprising a progressive ataxia of gait, parkinsonian features, limitation of conjugate gaze, fasciculations, areflexia, nystagmus, ataxic tremor, and extensor plantar responses; the pathologic changes closely resembled those described by Woods and Schaumburg. Romanul and coworkers compared the genetic, clinical, and pathologic features of their cases with those described in other Portuguese-Azorean families and concluded that all of them represent a single genetic entity with variable expression. This concept of the disease has been corroborated by the further observations of Rosenberg and of Fowler, who studied 20 patients with the Machado-Joseph-Azorean disease over a 10-year period.

This disease is not limited to Azoreans. Cases conforming to the above descriptions have now been observed among African-American, Indian, and Japanese families (Sakai et al, Yuasa et al, Bharucha et al). Cancel and colleagues have found an unstable number of CAG repeating sequences in a novel gene, ataxin-3, and named the disorder, which corresponds to Machado-Joseph disease, type 3 spinal cerebellar ataxia (SCA 3).

There is no treatment of proven value. Early diagnosis of patients at risk is possible by the examination of ocular movements. In asymptomatic patients, Hotson and associates found dysmetric horizontal and vertical saccades similar to those in symptomatic individuals. In fully developed cases, the MRI findings are characteristic—reduced width of the superior and middle cerebellar peduncles, atrophy of the frontal and temporal lobes, and smallness of the pons and globus pallidus (Murata et al).

**Multiple System Atrophy with Predominant Ataxia** (See page 925) This entity has been discussed with the degenerative dis orders of the basal ganglia earlier in the chapter. Here it is only pointed out again that a number of cases of sporadic progressive ataxia in mid- and late-life are attributable to this process and have been termed MSA-C to signify the predominant cerebellar feature. The extrapyramidal, corticospinal, or autonomic aspects of the illness become evident only with continued follow-up or by pathologic examination. Some guidance as to the frequency of MSA as the cause of otherwise undifferentiated sporadic ataxia is given in
briefly mentioned here are the hereditary ataxias, all rare, with sensory peripheral neuropathy (Biemond type with degeneration of dorsal root ganglia and posterior columns, of which we have seen two instances; see Nachmanoff et al); with optic atrophy; an autosomal recessive syndrome of cerebellar ataxia with pigmented retinal degeneration and congenital deafness; an autosomal dominant hereditary ataxia with muscular atrophy, retinal degeneration, and diabetes mellitus; Friedreich ataxia with juvenile parkinsonism; an autosomal recessive ataxia with total albinism; the autosomal recessive ataxia with cataracts, oligophrenia, pyramidal signs, and stunting of growth; and an essential (familial) tremor complicated in later years by cerebellar ataxia. Pollock and Kies have described yet another late-life form of hereditary cerebellar ataxia with near global loss of pain and temperature sensation (due to loss of primary sensory afferents). Details regarding these rare ataxias and appropriate references can be found in the monograph on the inherited ataxias edited by Kark et al.

Paroxysmal Ataxias Two adult forms of hereditary cerebellar ataxia are paroxysmal in nature (see Chap. 5). In one type (EA-2 for episodic ataxia, type 2), the episodes occur without explanation and last several hours; vertigo is usually a prominent feature of the attacks. Between attacks the patient is normal or has only minimal ataxia and nystagmus (Griggs et al). These ataxic episodes respond strikingly to oral acetazolamide. The disorder has been found to be a disorder of the calcium channel on chromosome 19. A similar but physiologically and genetically unrelated paroxysmal ataxia (EA-1) is characterized by episodes that may be precipitated by exercise and by muscle myokymia (rippling) between attacks. Vertigo does not occur and acetazolamide is less effective or not effective at all. The disorder is due to an abnormality of the potassium channel gene on chromosome 12. Both of these episodic ataxias are therefore “channelopathies” (see Chap. 54). Also of interest is spinocerebellar atrophy type 6, a progressive condition in which a mutation has been traced to same gene implicated in the EA-2 acetazolamide-responsive paroxysmal ataxia, but this disorder is not paroxysmal and results in progressive ataxia, dysarthria, and loss of proprioception.

Genetics of the Heredodegenerative Ataxias (Table 39-5)
The many familial degenerative ataxic disorders described in the preceding pages are genetically distinct. As indicated, autosomal recessive Friedreich ataxia is due to an expanded GAA repeat in the frataxin gene (Campuzano et al). The direct molecular test for the GAA expansion is useful for diagnosis, particularly for atypical cases with late onset (Dürr et al). The rarer recessive type associated with vitamin E deficiency arises from mutations in the gene that encodes an alpha tocopherol (vitamin E) transport protein, as mentioned above.

Among the autosomal dominant cerebellar ataxias of later onset, molecular and gene studies have identified mutant genes at 14 chromosomal loci, including three associated with episodic ataxia. Of these 14 forms of autosomal dominant ataxia, 8 are known to be caused by expanded CAG-trinucleotide repeats (SCA types 1, 3, 6, and 7, 12, 17, as well as dentatorubropallidoluysian atrophy, or DRPLA). Undoubtedly others will be discovered. However, as has been affirmed, the precise mechanisms by which the expanded polyglutamine molecule leads to neuronal cell death remain uncertain. It is likely that differences in the clinical manifestations of

Dentatorubropallidoluysian Atrophy (DRPLA) This is a rare familial disorder, described mostly in Japan and in small European pockets, in which symptoms of cerebellar ataxia are coupled with those of choreoathetosis and dystonia and, in isolated instances, myoclonus, parkinsonism, epilepsy, or dementia. Pathologically there is degeneration of the dentatorubral and pallidoluysian systems (Smith; Iizuka et al). The main consideration when chorea is prominent is the separation of this disorder from Huntington disease (Warner et al). The gene defect is an unstable CAG trinucleotide repeat on chromosome 12 that codes for polyglutamine in the gene and expresses the protein atrophin. This same mutation has been defined in families from throughout the world (e.g., Warner et al). As with Huntington chorea (where the expanded polyglutamine tract is in huntingtin), this disease is inherited as an autosomal dominant trait and shows an inverse correlation between the age of onset and the size of the gene expansion. Diagnosis can be confirmed by means of DNA analysis.

Other Complicated Hereditary Cerebellar Ataxias

Dentatorubral Degeneration This is a rare and still somewhat nebulous entity, but it is probably distinct from the condition described above, under “Dentatorubropallidoluysian Atrophy.” There are, however, several instructive features. In 1921, Ramsay Hunt published an account of 6 patients (2 of whom were twin brothers) in whom myoclonus was combined with progressive cerebellar ataxia. The age of onset in the 4 nonfamilial cases was between 7 and 17 years, and the cerebellar ataxia followed the myoclonus by an interval of 1 to 20 years. Hunt named this disorder dyssynergia cerebellaris myoclonica. In the twin brothers there were signs of Friedreich ataxia; postmortem examination of one showed a degeneration of the posterior columns and spinocerebellar tracts but not of the corticospinal tracts. The only lesion in the cerebellum was an atrophy and sclerosis of the dentate nuclei with degeneration of the superior cerebellar peduncles. Louis-Bar and van Bogaert in 1947 reported a similar case, and they noted, in addition to the above findings, degeneration of the corticospinal tracts and loss of fibers in the posterior roots. Thus the pathology was identical to that of Friedreich ataxia except for the more severe atrophy of the dentate nuclei.

Earlier (1914), under the title of dyssynergia cerebellaris progressiva, Hunt had drawn attention to a progressive disease in young individuals manifest by what he considered to be a pure cerebellar syndrome. One of the three patients described in this paper died 13 years after the onset of her illness. Necropsy disclosed cavity lesions in the lenticular nuclei, cerebellum, andpons and a diffuse increase of Alzheimer (type 2) glial cells, associated with asymptomatic nodular cirrhosis of the liver—i.e., findings typical of progressive lenticular degeneration (Wilson disease). Hunt’s reports emphasize the hazard of classifying cerebellar ataxias on the basis of clinical findings alone, a point made effectively by Holmes in relation to the hereditary cerebellar ataxia of Marie (see earlier).

Cerebellar Ataxia with Selective Degeneration of Other Systems In addition to those enumerated earlier on page 185),
these disorders will reflect differences in the patterns of expression of the affected proteins; i.e., each is expressed in different subpopulations of neurons and at different stages in development. This raises the possibility that the cascade of events that triggers neuronal degeneration is similar in each of the diseases with a CAG expansion and that a therapy might be discovered that is effective in all of them.

Table 39-5 summarizes the chromosomal loci, genetic terminology, related neural abnormalities, and clinical features of the CAG-dependent (and other) cerebellar atrophies.

The main types are summarized again here with some clinical comments:

SCA 1: 6p; ophthalmoparesis, pyramidal and extrapyramidal signs; included in this group are most of the olivopontocerebellar atrophies.

SCA 2: 12q; slowed eye movements and saccades (Wadia type).

SCA 3: 14q; the Machado-Joseph phenotype with several allelic variants.

SCA 4: 16q; sensory neuropathy and pyramidal signs.

SCA 7: 3p; retinal degeneration.

SCA 6: 19p; related to the alpha subunit of a voltage-dependent calcium channel; a different mutation at the same locus causes the acetazolamide-responsive episodic ataxia (EA-2).

EA-1: (episodic ataxia) 12p; potassium channelopathy.

EA-2: (acetazolamide-responsive episodic ataxia) 19p; calcium channelopathy.

**Differential Diagnosis of the Degenerative Ataxias** (See Table 5.1, Page 78)  
Sporadic forms of cerebellar ataxia in adults are in some instances traceable to strokes involving cerebellar pathways (Safe et al). These are, of course, of acute onset. Some cases of ataxia are alcoholic-nutritional in origin, and a few are related to abuse of drugs, especially anticonvulsants, which may in a few cases cause a slowly progressive and permanent ataxia; rarely, organic mercury induces subacute cerebellar degeneration, and adulterated heroin causes a more abrupt and severe ataxic syndrome. The paraneoplastic variety of cerebellar degeneration often enters into the differential diagnosis; as a rule it occurs mostly in women with breast or ovarian cancers and evolves much more rapidly than any of the heredodegenerative forms. The more rapid onset of ataxia and the presence of anti-Purkinje cell antibodies (anti-Yo; page 583) are central to identifying the nature of this disease. From time to time one observes a similar idiopathic variety of subacute cerebellar degeneration, particularly in women who have no neoplasm and lack the specific antibodies of the paraneoplastic disease (Ropper). Rare cases of ataxia have been associated with celiac disease and Whipple disease, as noted in Chap. 5. Ataxia may also be an early and prominent manifestation of Creutzfeldt-Jakob disease caused by a transmissible prion (see Chap. 33) or of an inherited metabolic disease (Chap. 37). Of the latter, late-onset GM2 gangliosidosis may simulate a cerebellar degeneration in adults (page 826). Rare cases of aminoacidopathy manifesting for the first time in adult life have also provoked a cerebellar syndrome.

**Treatment**  
This has been unsatisfactory and is limited largely to supportive measures such as the prevention of falling. Amantadine 200 mg daily for several months has shown limited benefit in some studies (Boetz et al). Whether thalamic electrical stimulators, or the type used for the treatment of Parkinson disease, have a role in suppressing the cerebellar tremor is not known.

**Hereditary Polymyoclonus**

The syndrome of quick, arrhythmic, involuntary single or repetitive twitches of a muscle or group of muscles was described in Chap. 6, where it was pointed out that the condition has many causes. Those due to hereditary metabolic diseases are presented in Chap. 37. Familial forms are known, one of which, associated with cerebellar ataxia, was discussed earlier (dyssynergia cerebellaris myoclonica of Ramsay Hunt). But there is another disease, known as hereditary essential benign myoclonus, that occurs in relatively pure form unaccompanied by ataxia (page 87). In the latter condition, it may at times be difficult to evaluate coordination because willed movement is interrupted by the myoclonus and may be mistaken for intention tremor. Only by slowing the voluntary movement can the myoclonus be reduced or eliminated. This myoclonic disease is inherited as an autosomal dominant trait. It becomes manifest early in life; once established, it persists with little or no change in severity throughout life, often with rather little disability. It can, by its natural course, be differentiated from some of the hereditary metabolic diseases such as the Unverricht and Lafora types of myoclonic epilepsy, the lipidoses, tuberous sclerosis, and myoclonic disorders that follow certain viral infections and anoxic encephalopathy. Of interest is the response of this form of movement disorder, as in the case of acquired postanoxic myoclonus (page 89), to certain pharmacologic agents, notably clonazepam, valproic acid, and 5-hydroxytryptophan, the amino acid precursor of serotonin, particularly when these agents are used in combination.

The main clinical distinctions to be made are from Creutzfeldt-Jakob subacute spongiform encephalopathy; drug-induced myoclonus, particularly lithium; renal failure and other acquired metabolic disorders; asterixis; and from the startle responses (page 90). Myoclonus as one component of a more complex movement disorder in corticobasal-ganglionic degeneration has already been mentioned.

**SYNDROME OF MUSCULAR WEAKNESS AND WASTING WITHOUT SENSORY CHANGES**

**Motor System Disease**

This general term is used to designate a progressive degenerative disorder of motor neurons in the spinal cord, brainstem, and motor cortex, manifest clinically by muscular weakness, atrophy, and corticospinal tract signs in varying combinations. It is a disease of middle life, for the most part, and progresses to death in a matter of 2 to 5 years or longer in exceptional cases.

Customarily, motor system disease is subdivided into several subtypes on the basis of the particular grouping of symptoms and signs. The most frequent form, in which amyotrophy and hyperreflexia are combined, is called *amyotrophic lateral sclerosis*, or ALS (amyotrophy is the term applied to denervation atrophy and weakness of muscles). Less frequent are cases in which weakness and atrophy occur alone, without evidence of corticospinal tract dysfunction; for these the term progressive spinal muscular atrophy is used. When the weakness and wasting predominate in muscles innervated by the motor nuclei of the lower brainstem (i.e., muscles of the jaw, face, tongue, pharynx, and larynx), it is customary to speak of progressive bulbar palsy. In a small proportion of patients, the clinical state is dominated by spastic weakness,
The best known is the Werdnig-Hoffmann type of most frequent form of serious autosomal recessive disease (Pearn). It occurs in infancy and childhood. Indeed, this condition is the lead-in to other neurologic signs.

spinal tracts or, in some cases, combined with posterior column or paraplegia in which the disease process is confined to the corticospinal pathways (Pringle et al). The present authors systematize a disease in which the degenerative process remains confined to the muscles atrophy called Charcot disease in France, a lucid account of the clinical and pathologic findings. Although disease. In a series of lectures given from 1872 to 1874, he provided a lucid account of the clinical and pathologic findings. Although called Charcot disease in France, amyotrophic lateral sclerosis (the term recommended by Charcot) has been preferred in the English-speaking world. Duchenne had earlier (1858) described labioglosaryngeal paralysis, a term that Wachsmuth in 1864 changed to progressive bulbar palsy. In 1869 Charcot called attention to the nuclear origin of progressive bulbar palsy, and in 1882 Déjerine established its relationship to ALS. Most authors credit Aran and Duchenne with the earliest descriptions of progressive spinal muscular atrophy, which they believed to be of myogenic origin. This interpretation was, of course, incorrect; Cruveilhier, a few years later, noted the slender anterior roots, and soon thereafter the disease was brought into line with ALS as a myopathic or spinal muscular atrophy.

Amyotrophic Lateral Sclerosis This is a common disease, with an annual incidence rate of 0.4 to 1.76 per 100,000 population. Men are affected nearly twice as often as women. Most patients are more than 45 years old at the onset of symptoms, and the incidence increases with each decade of life (Mulder). The disease occurs in a random pattern throughout the world except for a dramatic clustering of patients among inhabitants of the Kii peninsula in Japan and in Guam, where ALS is often combined with dementia and parkinsonism. In about 10 percent of cases, the disease is familial, being inherited as an autosomal dominant trait with age-dependent penetrance. The familial cases do not differ much in their symptoms and clinical course from nonfamilial ones, although as a group the former have a somewhat earlier age of onset, an equal distribution in men and women, and a slightly shorter survival.

In the most typical forms of disease, the onset is perceived by the patient as weakness in a distal part of one limb. This may be noted first as an unexplained tripping because of slight foot drop. Or there may be awkwardness in tasks requiring fine finger movements (in handling buttons and automobile ignition keys), stiffness of the fingers, and slight weakness or wasting of the hand muscles. In other words, features related to upper and to lower motor neuron degeneration (or both) may appear insidiously in one limb. Cramping beyond what seems natural and fasciculations of the muscles of the forearm, upper arm, and shoulder girdle also appear. The earliest manifestation of the lower motor neuron component of this disease is often volitional cramping—for example, leg cramps as the patient turns in bed during the early morning hours. (This is never a presenting complaint, but it is quite common as an early manifestation.) As the weeks and months pass, the other hand and arm may be similarly affected. Before long, the triad of atrophic weakness of the hands and forearms, slight spasticity of the arms and legs, and generalized hyperreflexia—all in the absence of sensory change—leaves little doubt as to the diagnosis. Muscle strength and bulk diminish in parallel or there is a relative preservation of power early in the illness. Despite the amyotrophy, the tendon reflexes are notable for their liveliness.

Coarse fasciculations are usually evident in the weakened muscles but may not be noticed by the patient until the physician calls attention to them. Fasciculations are almost never the sole presenting feature of ALS—a clinical truism with which one can reassure physicians and medical students who fear, on the basis of persistent focal muscle twitching, that they are developing the disease.

The affected parts may ache and feel cold, but true paresthesias, except from poor positioning and pressure on nerves, do not occur or are minor. Sphincteric control is well maintained even after both legs have become weak and spastic, but many patients acquire urinary and sometimes fecal urgency in the advanced stages of the disease. The abdominal reflexes may be elicitable even when the plantar reflexes are extensor. Extreme spasticity is rarely seen. Coarse fasciculations are usually evident in the weakened muscles but may not be noticed by the patient until the physician calls attention to them. Fasciculations are almost never the sole presenting feature of ALS—a clinical truism with which one can reassure physicians and medical students who fear, on the basis of persistent focal muscle twitching, that they are developing the disease.

The course of this illness, irrespective of its particular mode of onset and pattern of evolution, is progressive. There may be periods lasting weeks or months during which the patient observes no advance in symptoms but clinical changes can nonetheless be detected. Half the patients succumb within 3 years of onset and 90 percent within 6 years (Mulder et al). The clinical variants of motor neuron disease that occur with regularity and have distinguishing clinical features are described below.

Other Patterns of Evolution In addition to the special configurations discussed further on, there are many patterns of neuromuscular involvement other than the one just described. A leg may be affected before the hands. A foot drop with weakness and wasting of the pretibial muscles may be incorrectly attributed to peroneal nerve compression until weakness of the gastrocnemius and other muscles betrays a more widespread involvement of lumbosacral
neurons. In our experience this crural amyotrophy is somewhat less frequent than the brachial-manual type. Another variant is the early involvement of thoracic, abdominal, or posterior neck muscles, the last being one of the causes of head lolling in older individuals. Yet another pattern is of early diaphragmatic weakness; such cases come to attention because of respiratory failure. The pattern of more symmetrical proximal limb or shoulder-girdle amyotrophy with onset at an early age is also well known and simulates muscular dystrophy (Wohlfart-Kugelberg-Welander disease—page 946). On several occasions we have observed a pattern involving the arm and leg on the same side, first with spasticity and then with some degree of atrophy; this is sometimes called the hemiplegic or Mills variant. However, this condition more frequently turns out to be due to multiple sclerosis.

The first manifestations may be a spastic weakness of the legs, in which case a diagnosis of primary lateral sclerosis may be made (discussed further on); only after a year or two does the hand and arm muscles weaken, waste, and fasciculate. It is cases of this type that led to the inclusion of spastic paraparesis as a variant of ALS. Early on, a spastic bulbar palsy with dysartria and dysphagia, hyperactive jaw jerk and facial reflexes, but without muscle atrophy, may be the initial phase of disease.

From time to time, as the disease advances, very mild distal sensory loss is observed in the feet without explanation, but always, if the sensory loss is a definite and early feature, the diagnosis must remain in doubt. About 5 percent of cases of ALS are observed in conjunction with a frontotemporal dementia; less commonly, there is an association with a Parkinson syndrome (page 806).

**Progressive Muscular Atrophy (PMA)** This clinical syndrome is more common in men than in women, in a ratio of 4 to 1. It probably encompasses several diseases of the lower motor neuron, only some of which are manifestations of ALS. In fact, the original report of familial PMA by William Osler described a family now known to have a mutation in the SOD1 gene (see below). In about half the patients, the illness takes the form of a symmetrical (sometimes asymmetrical) wasting of intrinsic hand muscles, slowly advancing to the more proximal parts of the arms; less often, the legs and thighs are the sites of the initial atrophic weakness; less often still, the proximal parts of the limbs are affected before the distal parts. Fascicular twitchings and cramping are variably present.

These purely lower motor neuron amyotrophies tend to progress at a slower pace than the usual case of ALS, some patients surviving for 15 years or longer. Chio and colleagues, who analyzed the factors affecting life expectancy in 155 patients with PMA, found that younger patients had a more benign course—the 5-year survival was 72 percent in patients with an onset before age 50 and 40 percent in patients with onset after age 50. Some of the most chronic varieties of PMA are familial. Otherwise they differ from ALS only in that the tendon reflexes are diminished or absent and signs of corticospinal tract disease cannot be detected. The main disease to be distinguished from PMA is an immune-mediated motor neuropathy that occurs with or without multifocal block of electrical conduction (page 1099) and various muscle diseases, notably, inclusion body myopathy. The presence of a paraproteinemia, specifically IgM with antibodies against the GM1 ganglioside, or the finding of focal conduction block or sensory nerve abnormalities on the EMG implies the presence of an autoimmune neuropathy disease rather than one of motor neuron type, as discussed on page 1149.

**Progressive Bulbar Palsy** Here reference is made to a condition in which the first and dominant symptoms relate to weakness and laxity of muscles innervated by the motor nuclei of the lower brainstem, i.e., muscles of the jaw, face, tongue, pharynx, and larynx. This weakness gives rise to an early defect in articulation, in which there is difficulty in the pronunciation of lingual (r, n, l), labial (b, m, p, f), dental (d, t), and palatal (k, g) consonants. As the condition worsens, syllables lose their clarity and run together, until finally the patient’s speech becomes unintelligible. In other patients, slurring is due to spasticity of the tongue, pharyngeal, and laryngeal muscles; the speech sounds as if the patient were eating food that is too hot. Usually the voice is modified by a combination of atrophic and spastic weakness, as indicated below. Defective modulation of the voice with variable degrees of rasping and nasality is another characteristic. The pharyngeal reflex is lost, and the palate and vocal cords move imperfectly or not at all during attempted phonation. Mastication and deglutition also become impaired; the bolus of food cannot be manipulated and may lodge between the cheek and teeth; and the pharyngeal muscles do not force it properly into the esophagus. Liquids and small particles of food find their way into the trachea or nose. The facial muscles, particularly of the lower face, weaken and sag. Fasciculations and focal loss of tissue of the tongue are usually early manifestations; eventually the tongue becomes shrunken and lies useless on the floor of the mouth. The chin may also quiver from fascicular twitchings, but diagnosis of the disease should not be made on the basis of fasciculations alone, i.e., in the absence of weakness or atrophy. The jaw jerk may be present or exaggerated at a time when the muscles of mastication are markedly weak. In fact, spasticity of the jaw muscles may be so pronounced that the slightest tap on the chin will evoke clonus and blinking; rarely, attempts to open the mouth elicit a “bulldog” reflex (jaws snap shut involuntarily). Commonly, when a jaw jerk is present, a positive snout reflex can also be detected, both of these reflect degeneration of the posterior frontal lobe. Spastic weakness of the oropharyngeal muscles may be the initial manifestation of bulbar palsy and may at times surpass signs of atrophic weakness: pseudobulbar signs (pathologic laughter and crying) may reach extreme degrees. This is the only common clinical situation in which spastic and atrophic bulbar palsy coexist. Strangely, the ocular muscles always escape.

As with other forms of motor system disease, the course of bulbar palsy is inexorably progressive. Eventually the weakness spreads to the respiratory muscles and deglutition fails entirely; the patient dies of inanition and aspiration pneumonia, usually within 2 to 3 years of onset. About 25 percent of cases of motor system disease begin with bulbar symptoms, but rarely if ever does the sporadic form of progressive bulbar palsy run its course as an independent syndrome (pure heredofamilial forms of progressive bulbar palsy in the adult are known but rare). Practically always, after a few months or more, the other manifestations of ALS become evident. In general, the earlier the onset of the bulbar involvement, the shorter the course of the disease. Treatment is discussed below.

**Primary Lateral Sclerosis (PLS)** This entity, like ALS, can be a form of motor neuron disease, although we consider most cases to be examples of a separate process. Many but by no means all patients in whom the signs of corticospinal tract degeneration betray the presence of ALS will develop indications of lower motor neuron disease within 1 year, usually earlier. Approximately 20 percent of these patients, however, have a slowly progressive cor-
ticospinal tract disorder that begins with a pure spastic paraparesis; later, and to a lesser degree, the arms and oropharyngeal muscles become involved. These cases have distinctive neuropathologic features and are designated as primary lateral sclerosis, a term originally suggested by Erb in 1875. A historical review of the subject appears in the article by Pringle and colleagues. The features that most distinguish these cases from hereditary spastic paraparesis (HSP) is the onset during adulthood and the involvement of the arms and oropharyngeal muscles; the latter are almost universally spared in HSP.

The typical case begins insidiously in the fifth or sixth decade with a stiffness in one leg, then the other; there is a slowing of gait, with spasticity predominating over weakness as the years go on. Walking is still possible with the help of a cane for many years after the onset, but eventually this condition acquires the characteristic features of a severe spastic paraparesis. Over the years, finger movements become slower, the arms become spastic, and, if the illness persists for decades, speech takes on a pseudobulbar tone. In some patients the illness evolves over a few years. There are no sensory symptoms or signs. The legs are often found to be surprisingly strong, the difficulty in locomotion being attributable mainly to rigid spasticity. About half the patients acquire spasticity of the bladder. Pringle and associates suggest that an important diagnostic criterion of the disease is progression for 3 years without evidence of lower motor neuron dysfunction. A rare type begins in the oropharyngeal muscles, as mentioned above, but almost always, atrophy and fasciculations in this same region are evident within months.

Laboratory studies are seldom helpful. In a few instances we have been able to detect changes in the spinal course of the corticospinal tract on FLAIR MR images, but the majority of our other cases showed no such changes. Several authors have emphasized prolonged motor evoked potentials and conspicuous precentral atrophy on MRI (see Kuipers-Upmeijer et al). The spinal fluid and CK level are normal and the EMG reveals no indications of neuromuscular denervation unless the spasticity is simply the initial feature of ALS.

Pathologic studies in a limited number of cases have disclosed a relatively stereotyped pattern of reduced numbers of Betz cells in the frontal and prefrontal motor cortex, degeneration of the corticospinal tracts, and preservation of motor neurons in the spinal cord and brainstem (Beal and Richardson, Fisher, Pringle et al). The corticospinal tract lesions are identical to those in typical ALS, described further on. Whether some of these cases are examples of late-onset familial spastic paraplegia (see further on) has not been explored with molecular techniques.

Differential Diagnosis of PLS Some patients who have only restricted bilateral signs of upper motor neuron disease prove to have multiple sclerosis, a slow compression of the spinal cord by spondylosis or meningioma, or the myelopathic form of adrenoleukodystrophy (affected males or female carriers). In a few, tropical spastic paraplegia, HIV myelopathy, or a family history of spastic paraplegia (Strümpell-Lorrain disease, described further on) has been uncovered. Almost unique among cases of this type have been a few linked to an adult onset of phenylketonuria or other aminoacidopathies, or to vitamin B<sub>12</sub> deficiency.

Laboratory Features of Motor Neuron Disease Laboratory investigation provides useful confirmatory evidence even in the typical clinical syndrome. The EMG, as expected, displays widespread fibrillations (evidence of active denervation) and fasciculations and enlarged motor units (denoting reinnervation), and motor nerve conduction studies reveal only a slight slowing, without focal motor conduction block. If the atrophic paresis is restricted to an arm or hand, raising the question of cervical spondylosis, evidence of denervation over many widely separated somatic segments favors the diagnosis of ALS. In questionable cases, it is good practice to insist that denervation be demonstrated in at least three limbs before concluding that the process is ALS. (The currently favored criteria used for the purposes of clinical research mandate that this finding be present.) Widespread denervation of the paraspinal muscles and genioglossus or facial muscles is also strongly indicative of the disease, but testing of these muscles demands considerable experience. A muscle biopsy is sometimes helpful in corroborating neurogenic denervation. Sensory nerve action potentials should be normal; tests of motor nerve conduction have a normal velocity, but the amplitudes become progressively lower as the disease progresses—in the earliest stages, they too may be normal. When in a typical case the amplitudes of sensory nerve action potentials are reduced, there is usually an underlying entrapment neuropathy, diabetes, or late-life neuropathy. Sensory evoked potentials are mildly abnormal in a proportion of patients, but the explanation for this finding is obscure. (Sensory complaints and minimal sensory loss have been commented on above.) The CSF protein is usually normal or marginally elevated. Serum creatine kinase is moderately elevated in patients with rapidly progressive atrophy and weakness, but it is just as often normal. Motor evoked potentials elicited from the cortex are also prolonged in patients with prominent corticospinal signs. In this group, the MRI may show slight atrophy of the motor cortices and wallerian degeneration of the motor tracts (Fig. 39-9). These changes may be diagnostically useful and appear as increased FLAIR and T2 signal intensity in the posterior limb of the internal capsule, descending motor tracts of the brainstem, and spinal cord, all of which are subtle and may be missed.

Pathology The principal finding in ALS is a loss of nerve cells in the anterior horns of the spinal cord and motor nuclei of the lower brainstem. Large alpha motor neurons tend to be affected before small ones. In addition to neuronal loss, there is evidence of slight gliosis and proliferation of microglial cells. Many of the surviving nerve cells are small, shrunken, and filled with lipofuscin. It is not uncommon to also detect ubiquitin inclusions in threads, skeins, or dense aggregates within the affected neurons by special stains. Occasionally, there is another ill-defined cytoplasmic inclusion body. According to some reports, swelling of the proximal axon is an early finding, presumably antedating visible changes in the cell body itself. The anterior roots are thin, and there is a disproportionate loss of large myelinated fibers in motor nerves (Bradley et al). The muscles show typical denervation atrophy of different ages. Whitehouse and coworkers found a depletion of muscarinic, cholinergic, glycnergic, and benzodiazepine receptors in regions of the spinal cord where motor neurons had disappeared.

The corticospinal tract degeneration is most evident in the lower parts of the spinal cord, but it can be traced up through the brainstem to the posterior limb of the internal capsule and corona radiata by means of fat stains, which show the macrophages that accumulate in response to myelin degeneration. There is a loss of Betz cells in the motor cortex; this is manifest as a slight frontal lobe atrophy on the MRI, but it is not a prominent finding in most cases of ALS (Kierman and Hudson). Other fibers in the ventral and lateral funiculi are depleted, imparting a characteristic pallor in myelin stains. Some pathologists have interpreted this as evi-
cases have shown an extensive neuronal loss, gliosis, and vacuolation involving the frontal premotor area, particularly the superior frontal gyri and the inferolateral cortex of the temporal lobes. The histologic changes of Alzheimer or Pick disease have not been seen in our cases; neurofibrillary degeneration has been observed but is inconsequential in comparison to that seen in the Guamanian Parkinson-dementia-ALS complex (Finlayson et al; Mitsuyama). Attempts to transmit this ALS-dementia syndrome to subhuman primates have been unsuccessful.

**Differential Diagnosis of ALS** The clinical picture of motor system disease may be simulated by a central spondylotic bar or ruptured cervical disc, but with these conditions there is usually pain in the neck and shoulders, limitation of neck movements, and sensory changes, and the lower motor neuron changes in spondylitis are restricted to one or two spinal segments. The EMG is helpful if not decisive in differentiating these disorders. A mild hemiparesis or monoparesis due to multiple sclerosis may for a time be difficult to distinguish from early ALS. Progressive spinal muscular atrophy may be differentiated from peroneal muscular atrophy (Charcot-Marie-Tooth neuropathy) by the lack of family history, the complete lack of sensory change, and different EMG patterns. Motor system disease beginning in the proximal limb muscles may be misdiagnosed as a limb-girdle type of muscular dystrophy. The main considerations in relation to progressive bulbar palsy are myasthenia gravis and, less often, polymyositis, muscular dystrophy, and especially the inherited (Kennedy) type of bulbospinal atrophy, which is discussed further on. The spastic form of bulbar palsy may suggest the pseudobulbar palsy of lacunar disease. A crural form of PMA may be confused with diabetic polyradiculopathy or polymyositis.

As already mentioned, a major consideration is the differentiation of PMA from a chronic motor polyneuropathy, particularly the form that displays multifocal conduction block. Extensive nerve conduction studies and needle EMG examinations are necessary to distinguish the two; these neuropathic processes are discussed with the peripheral neuropathies in Chap. 46. The presence of an IgM monoclonal paraproteinemia or of specific antibodies directed against GM1 are indicative of the immune motor neuropathy, but in half of the cases the tests are negative. There is also a rare form of subacute poliomyelitis (possibly viral) in patients with lymphoma or carcinoma; it leads to an atrophy that progresses to death over a period of several months. For further discussion of the paraneoplastic variety of motor system disease, see page 585.

Because it may produce a motor-predominant radiculopathy, chronic Lyme infection is sometimes considered in the differential diagnosis of ALS. Some clinics screen for Lyme antibodies using both an enzyme-linked immunosorbent assay (ELISA) and the more sensitive and specific Western immunoblot, but we have never detected such a case. Infrequently, we have seen myelopathic motor findings and motor radiculopathy with vitamin B12 deficiency, and there are exceptional reports of myeloradicular neuropathy with lead poisoning; we sometimes include tests for these conditions. Another entity that may simulate ALS is inclusion body myositis (IBM)—an atypical myopathy that begins asymmetrically and involves distal muscles, usually without much elevation of serum CPK levels. In a recent series of 70 patients with this condition, 13 percent were initially diagnosed as having ALS (Dabby et al). Features distinguishing the IBM cases included normal corticospinal signs, preservation of deep tendon reflexes in weak mus-
cles, and finger flexor weakness. One concludes from this series that a detailed, quantitative EMG and possibly a muscle biopsy are indicated in cases that display predominantly lower motor features. Fully developed ALS is difficult to confuse with these conditions. Acid maltase deficiency may also simulate ALS in causing fati-
gability and early respiratory failure.

Over the years, the authors have occasionally encountered young men with localized and asymmetrical atrophy of the leg or arm that became arrested and did not advance over a decade or two. Several reports of such a partial spinal atrophy have appeared in recent years (Hirayama et al; Moreno Martinez et al). In the type described by Hirayama, young men are affected with pro-
gressive and asymmetrical atrophy of the forearm and hand that has been traced to ligamentous hypertrophy in the ventral spi-
nal canal. This causes a compression of the cervical spinal cord, presumably a chronic ischemic effect (page 1077). In a familial variety of pure restricted atrophy, only the vocal cords became paralyzed over a period of years in adult life; only later were the hands affected.

Some patients who have recovered from paralytic poliomyel-
litis may develop progressive muscular weakness 30 or 40 years later; the nature of this relationship is obscure. We favor the ex-
planation that atrophy of anterior horn cells with aging brings to light a critically depleted motor neuron population (see further on). It appears to progress little if at all.

An observation of interest is the finding of a form of progres-
sive spinal muscular atrophy in patients with GM1 gangliosidosis, the storage disease that presents in infancy as Tay-Sachs disease (Kolodny and Raghavan). The onset is in late adolescence and early adult life and the atrophic paralysis is progressive, so that this con-
tion is often mistaken for Wohlfart-Kugeberg-Welander disease or ALS. A number of cases of this type have been discovered in Ashkenazi Jews by the use of lysosomal enzyme analysis.

An estimate of the frequency of all the aforementioned alter-
native diagnoses that have been exposed by the study of cases that were initially presumed to be PMA but turned out to represent another process is given by Visser and colleagues. In 17 of 89 patients the initial diagnosis of PMA proved in the end to be due to anti-GM1 motor conduction block, chronic inflammatory de-
myelinating polyneuropathy, and various myopathies. This not-
withstanding, ALS or the more discrete forms of motor system disease rarely offer any difficulty in diagnosis.

Pathogenesis  The pathogenesis of the sporadic form of motor system disease is not known. Some insight has been afforded by analyses of the 10 percent of ALS cases that are inherited in an autosomal dominant pattern (see Table 39-6). Of these, about 25 percent harbor mutations in a gene that codes for the cytosolic enzyme Cu-Zn superoxide dismutase (SOD1) (Rosen et al) More than 100 different mutations have been identified in this gene. SOD1 is extremely abundant, accounting for perhaps 0.5 percent of all cytoplasmic protein. It is therefore not surprising that several aspects of neuronal function are compromised by the toxic prop-
erties of the mutant SOD1 protein. Recent studies have revealed that the demise of motor neurons is a consequence of pathology in both the motor neurons themselves and in the surrounding non-
neuronal cells (Clement et al). Current evidence supports the notion that mutant SOD1 protein aggregates cause excitotoxic glutami-
ergic activity and mitochondrial dysfunction. Confirmation has been sought in the putative response of experimental models of ALS to treatment with glutamate blockers (see further on). The SOD1 gene is not, however, mutated in sporadic cases.

An even rarer and recessively inherited childhood form of motor neuron disease (affecting corticospinal more than spinal mo-
tor neurons) has been attributed to mutations in a gene whose pro-
tein (alsin) is a component of the neuronal cell-signaling pathways. Yet another rare childhood-onset form of disease arises from mu-
tations in the sentaxin gene, a DNA helicase that probably assists in chromatin folding and unfolding. (It is of interest that a reces-
sively inherited mutation in the same gene transmits a recessive form of ataxia with oculomotor disorder.) In several families, a mutation has been detected in a protein that is involved in the transport of vesicles in neurons. A case of ALS with prominent corticospinal signs has been described in an individual with a novel mutation in the mitochondrial gene for cytochrome-c oxidase. These various genetic forms of motor neuron disease are summar-
ized in Table 39-6. It is apparent that the cellular mechanisms that sustain motor neurons can be disrupted at several sites. Whether some derangement of the SOD1 protein that arises during aging contributes to the pathogenesis of the sporadic type is unknown, but study of this mutation, and of the rare inherited childhood forms of ALS, is providing provocative avenues for research.

Trauma, particularly traction injury of an arm, has been re-
ported occasionally as an antecedent event in patients with ALS, but a causative relationship has not been established. Younger and coworkers have found a higher incidence of paraproteinemia in patients with motor system disease than can be accounted for by chance. Many other examples of disordered immune function have been described in patients with motor system disease, but a coherent explanation of ALS as an autoimmune disease has not emerged. It has never been proved that intoxication with heavy metals (lead, mercury, aluminum) can cause motor system disease, although there are reports of concurrent myelopathic and radicular motor signs in patients with lead intoxication. There is little evidence that such cases represent a reactivation of the virus or the presence of some other infectious agent. The progressive weakness that occurs some 30 to 40 years after recovery from polio should not be con-
fused with PMA, as indicated above. Finally, we have had occasion to see two patients who, many years after a severe electrical injury that passed through the region of the cord, developed a progressive and severe amyotrophy of the arms; other such cases are known (see page 1056).

Treatment  With the exception of riluzole, discussed below, there is no specific treatment for any of the motor neuron diseases. Sup-
portive measures, however, are exceedingly important. In initial office visits, it has been our practice to give the patient some idea of the seriousness of the condition; but in early discussions we avoid the devastating statement that ALS is invariably fatal. Typ-
ically, patients and family members will ask explicitly about these matters in subsequent visits; such data as are appropriate to the patient’s circumstances and character can be conveyed at that time, usually with the caveat that any individual may outlive the standard survival statistics.

The antiglutamate agent riluzole was shown by Bensimon and colleagues to slow the progression of ALS and improve survival in patients with disease of bulbar onset. However, it added only 3 months of life at best. This claim has been confirmed in several follow-up studies, although again the benefit has been marginal. Several additional agents are reported to have been effective in an SOD1 transgenic model of ALS. These are presently undergoing

study in ALS patients. Guanidine hydrochloride and injections of cobra venom, gangliosides, interferons, high-dose intravenous cytochrome-c oxidase, and thyrotropin-releasing hormone are but some of a long list of agents that are said to arrest the disease process, but these claims have been discredited.

An attempt can be made to reduce the spasticity with medications, such as baclofen or tizanidine, or by subarachnoid infusions of baclofen via an implanted lumbar pump. Initial intrathecal test doses are given to predict a response to the pump infusions of baclofen, but this test may fail; in severe cases it may therefore be advisable to proceed with a constant infusion for several days. Some degree of improved comfort from a reduction in the extreme rigidity is usually the most that can be expected. Some relief from spasticity may also be afforded by the use of benzodiazepines or sometimes dantrolene. These approaches are most suitable for cases of primary lateral sclerosis, which can be expected to progress slowly and for a long period.

At all stages of ALS, physical therapy is useful in maintaining mobility, but overwork of the muscles leading to fatigue and cramps should be avoided. Physical therapy is invaluable, for example, for avoiding contractures of the fingers and shoulders. Occupational therapy is likewise helpful, particularly assessments of the patient’s function in the home.

Important in the management of ALS is periodic monitoring of respiratory function. We typically perform pulmonary function tests every few months after the first year or so of illness. Our experience has been that the vital capacity in cubic centimeters can be estimated by multiplying the highest number to which a patient can count with one deep breath by 100. Thus, the ability to count to 25 with a full effort in a single breath corresponds to a vital capacity of approximately 2.5 L. Significant practical advances have been made in the respiratory management of ALS. The introduction of bimodal positive airway pressure (BIPAP) has allowed patients to sleep better and reduce daytime somnolence. Many patients do not initially tolerate the device, usually because of maladjusted face masks or excessive applied airway pressures. Almost always, a seasoned pulmonary technologist can find solutions to these problems. It is appropriate to begin BIPAP at (or before) the earliest sign of carbon dioxide retention, a state that is heralded by disruption of sleep, nightmares, early morning headaches, and daytime drowsiness. The second device that has greatly improved respiratory care in these patients has been the “Cough Assist” machine (Emerson), essentially a device that executes an artificial cough by first insufflating the lungs and then rapidly applying negative pressure, thereby facilitating clearing of the airways. It has been our impression that patients with weak diaphragms can reduce the frequency of pneumonia by the twice-daily use of this device.

With this type of noninvasive respiratory assistance, it may be possible to defer tracheostomy for months or years. Ultimately, as the diaphragm fails, BIPAP is needed not only at night but also during the day. As BIPAP use approaches 20 to 24 h per day, patients must usually address the difficult question of tracheostomy and mechanical ventilation. We broach this subject early enough in the course of the disease to allow ample time for discussion and reflection. Particularly with access to information on the Internet, many patients are well informed about these issues. In practice, most patients elect not to undergo tracheostomy and full ventilation.

Another important issue regards nutrition. As oropharyngeal palsy progresses, food should be cut into small pieces and dry foods, such as toast, avoided; milk shakes and preparations of the same consistency are ideal at this stage. Speech therapists are capable of teaching patients methods to adapt to declining bulbar function and at the same time minimizing aspiration. Ultimately in our experience, virtually every ALS patient will need a feeding tube to maintain normal hydration and caloric intake. While we adopt a neutral position regarding full ventilation, we tend to urge patients to undergo placement of a feeding tube. This clearly increases survival and improves quality of life by preventing dehydration and recurrent aspiration. Laparoscopic and radiologic technologies for the placement of a gastrostomy tube render the procedure swift and nearly painless. Some patients have tubes inserted as outpatients and then start gastric feeding within a day or two.

Other devices, often guided by the physical and occupational therapist, may be of great assistance to the patient and family as the disease progresses. These include a mechanized bed and structural accommodations in the home that facilitate entry of a wheelchair and the safe use of the bath or shower as well as thick-handled utensils. Ambulation aids, beginning with simple canes (first one, then two) followed by a walker (preferably with basket and seat) and then a wheelchair (manual or electric) are of value in maintaining a sense of independence and assuring safety.

As the disease enters its later stages, facile access to the neurologist and, if desired, regular visits for advice are very reassuring to the patient and family. Hospice-type care is often needed in the last weeks of illness for patients who can otherwise be cared for at home, and morphine or similar drugs as well as anxiolytic agents should be used liberally to ease discomfort, respiratory distress, and anxiety in the final days.
Heredofamilial Forms of Progressive Muscular Atrophy

These diverse diseases are the concern mainly of child neurology. They are presented here because they fall within the category of system degenerations, often of heredofamilial type.

Spinal Muscular Atrophy  The classic form of spinal muscular atrophy of hereditary type was first described by Werdnig in 1891 and 1894, by Hoffmann in 1893, and, at about the same time by Thomsen and Bruce. The cases described by these authors all involved infants. Further clinical analyses, however, indicated the inadequacy of this narrow grouping. Brandt, in his study of 112 Danish patients, found that in about one-third the weakness was present at birth, and in 97 the onset was in the first year of life; in 9 patients, the disease was not recognized until after the first year of life. In 1956 Walton, and later Wohlfart and colleagues and Kugelberg and Welander (see below), identified milder forms of spinal muscular atrophy in which the onset was between 2 and 17 years and walking was still possible in adult life. Byers and Banker, in a study of 52 patients, subdivided them into three groups on the basis of age of onset; in one group the disease was recognized at birth or in the first month of life; in a second, between 6 and 12 months; and in a third, after the first year. In their last group, it was not unusual for the patient to survive into adolescence and adult life. In a few of the late-onset types, signs of corticospinal tract involvement are conjoined, and Bonduelle has also included some patients with areflexia, pes cavus, Babinski signs, choreiform movements, and mental retardation in this group. More recently, the designations SMA I, II, and III have been introduced, based largely on the age of onset (Table 39-7).

Genetic Aspects of Spinal Muscular Atrophies  Familial spinal muscular atrophy that begins in infancy and childhood is inherited mainly as an autosomal recessive trait. All the SMA phenotypes in children have been mapped to the same chromosome: 5q11.2-13.3 (Brzustowicz et al; Gilliam et al; Munsat et al). SMA-associated mutations affect the gene at what has been termed the “survival of motor neuron” (SMN) site. The SMN protein participates in forming protein-RNA complexes (so-called small nuclear ribonucleoproteins and RNA) that are essential for gene splicing. Within the SMN locus there are two genes: SMN1, which generates a full-length, fully functional form of SMN, and SMN2, which makes a truncated, partially functional SMN. Making matters more complex, some individuals have more than two copies of SMN2. As a result, loss of both copies of SMN1 may cause very severe SMA in some individuals (in whom only one copy of SMN2 compensates for loss of SMN1), while others with multiple copies of SMN2 have milder disease. Thus, the amount SMN1 and SMN2 protein determines the severity of disease. Affected siblings demonstrate very similar clinical patterns of disease. However, the same gene error gives rise to very different phenotypes in different families, so that modifying posttranscriptional or nongenetic attributes must be playing a role. Less often, autosomal dominant and X-linked patterns of inheritance have been found, usually in adults.

Clinical Manifestations of Early-Onset Classic Werdnig-Hoffmann Type; SMA I  The most frequent form of these spinal muscular atrophies, the severe infantile type, is a common disease, occurring once in every 20,000 live births. After cystic fibrosis, it is the most frequent cause of death from a recessively inherited disease. Characteristically the infant, usually born normally, is noted from birth to be unnaturally weak and limp (“floppy”). Some mothers report that fetal movement in utero had been less than expected or lacking altogether. In severe cases, arthrogryposis at the ankles and wrists or dislocation of the hips is noted at birth (page 1244). The muscle weakness in these children is generalized from the beginning, and death comes early, usually within the first year. Other infants seem to develop normally for several months before the weakness becomes apparent. In these, the trunk, pelvic, and shoulder-girdle muscles are at first disproportionately affected, while the fingers and hands, toes and feet, and cranial muscles retain their mobility. Hypotonia accompanies the weakness, and since passive displacement of articulated parts in testing muscle tone is easier to judge than power of contraction at this early age, it may be singled out as the dominant clinical characteristic. As a

</table>
rule the tendon reflexes are unobtainable. Volume of muscle is diminished but is difficult to evaluate in the infant because of the coverings of adipose tissue. Fasciculations are seldom visible except sometimes in the tongue. Perception of tactile and painful stimuli is undiminished, and emotional and social development measure up to age.

As the months pass, the weakness and hypotonia progress gradually and spread to all of the skeletal muscles except the ocular ones. Intercostal paralysis with a degree of collapse of the chest is the rule. Respiratory movements become paradoxical (abdominal protrusion with chest retraction). The cry becomes feeble, and sucking and swallowing are less efficient. Such infants are unable to sit unless propped, and they cannot hold up their heads without support. They cannot roll over or support their weight when placed on their feet. Their posture is characteristic: arms abducted and flexed at the elbow, legs in the “frog position” with external rotation and abduction at hips and flexion at hips and knees. If the effects of gravity are removed, all muscles continue to contract; i.e., there is paresis, not paralysis. Until late in the illness, these children appear bright-eyed, alert, and responsive.

The disease runs a steadily downhill course. Infants in whom the disease becomes apparent only after several months of life have a less rapid decline than those affected in utero or at birth. Some of the former become able to sit and creep and even to walk with support; those with later onset may survive for several years and even into adolescence or early adult life, as already mentioned.

Laboratory data of confirmatory value are few. Muscle enzymes in the serum are usually normal, rarely elevated. The EMG, if performed at a late enough stage of development, displays fibrillations, proving the denervative basis of the weakness. Motor unit potentials are diminished in number and, in the more slowly evolving cases, some are larger than normal (giant or polyphasic potentials reflecting reinnervation). Motor nerve conduction velocities are normal or fall in the low-normal range (these are normally slower in infants than in adults). Early electrophysiologic studies may also give ambiguous results.

**Pathologic Findings** Muscle biopsy after 1 month of age reveals a typical picture of group atrophy; shortly after birth this change is difficult to discern. Aside from denervative atrophy, the essential abnormalities are in the anterior horn cells in the spinal cord and the motor nuclei in the lower brainstem. Nerve cells are greatly reduced in number, and many of the remaining ones are in varying stages of degeneration; a few are chromatolytic and contain cytoplasmic inclusions. It is not unusual to see figures of neurophagia. There is replacement gliosis and secondary degeneration in roots and nerves. Other systems of neurons, including the corticospinal and corticobulbar systems, remain intact.

**Differential Diagnosis** The major problem in diagnosis is to distinguish Werdnig-Hoffmann disease from an array of other diseases that cause hypotonia and delayed motor development in the neonate and infant. The list of disorders that imitates spinal muscular atrophy constitutes a large part of the differential diagnosis of the so-called floppy infant. The congenital myopathies (as described in Chap. 52), the glycogenoses, and disorders of fatty acid metabolism frequently present in this way. The preservation of tendon reflexes and relative lack of progression of muscle weakness distinguish the latter disorders. Because of the gravity of the diagnosis, muscle biopsy should be performed if there is any suspicion of spinal muscular atrophy. If studied properly, the biopsy usually yields the correct diagnosis.

Clinical disorders more or less similar to the spinal muscular atrophies may be identified occasionally in certain hereditary metabolic diseases. For example, Johnson and coworkers have described a patient who began experiencing weakness of the legs, cramping, and fasciculations during adolescence in what proved to be a variant of hexosaminidase A (GM1) deficiency, and biopsy of rectal mucosa showed nerve cells with the typical membranous cytoplasmic bodies of Tay-Sachs disease. Others have reported similar cases. A progressive motor neuron or motor nerve disorder has also been observed in glycerogen storage disease affecting anterior horn cells. Motor nerve fibers also suffer damage in metachromatic and globoid body leukoencephalopathies, and this may occur in adults, in association with paraproteinemia and multiple myeloma and as a paraneoplastic process.

Certain forms of muscular dystrophy, notably myotonic dystrophy, which is about twice as frequent as Werdnig-Hoffmann disease, may become manifest in the neonatal period and interfere with sucking and motor development (Chap. 52). As a rule, the weakness is not as severe or diffuse as that in Werdnig-Hoffmann disease. The mother, but not the child, may display myotonia, either elicitable clinically or, if more subtle, with EMG recording. Also, a number of polyneuropathies may cause a serious degree of weakness in early childhood. Unfortunately, in respect to the latter, adequate sensory testing is not possible because of the patient’s age, but the CSF protein is often elevated. Again, diagnosis is greatly facilitated by nerve-muscle biopsy and measurement of nerve conduction velocities. These velocities are reduced but must be interpreted with caution because of incomplete development of axons and of myelination in the first months of life. The needle EMG examination shows subtle signs of denervation that cannot be easily distinguished from the finding in the spinal muscular atrophies. Examination of parents and siblings may disclose a clinically inapparent neuropathy. Polymyositis of childhood may also simulate both muscular dystrophy and motor neuron disease (page 1205).

Mental retardation with a flaccid rather than spastic weakness of the limbs is another major category of disease that must be distinguished. Also, certain of the polioencephalopathies and leukodystrophies may weaken muscles and abolish tendon reflexes, but usually there is evidence of cerebral involvement. The same may be said of the Down syndrome, cretinism, Prader-Willi syndrome, and achondroplasia. Finally, very sick children with cerebral disease, cystic fibrosis, and other chronic diseases may be hypotonic to the point of simulating neuromuscular disease. Usually speech is not delayed and tendon reflexes are preserved in these purely medical states, and strength returns as the medical problem is corrected.

There remains, after the assiduous study of the “floppy infant,” a group of cases of hypotonia and motor underdevelopment that cannot be classified. The term *amyotonia congenita* (Oppenheim) was once applied to all of this group but is now obsolete. Walton proposed the term *benign congenital hypotonia* to designate patients who manifest limp and flabby limbs in infancy and a delay in sitting up and walking but who improve gradually, some completely and others incompletely. Neither of these terms serves the purpose of precise diagnosis. It is likely that among this group there are other examples of congenital myopathy that await differentiation by application of modern histochemical, ultrastructural, and genetic techniques.

**Chronic Childhood and Juvenile Proximal Spinal Muscular Atrophy (Wohlfart-Kugelberg-Welander Syndrome)** This is a somewhat different form of heredofamilial spinal muscular atrophy, which, as the name indicates, involves the proximal muscles.
of the limbs predominantly and is only slowly progressive. It was first clearly separated from other forms of motor system disease and from muscular dystrophy by Wohlfart and by Kugelberg and Welander in the mid-1950s. In about one-third of the cases, the onset is before 2 years of age, and in half, between 3 and 18 years. Males predominate, especially among patients with juvenile and adult onset. The usual form of transmission is by an autosomal recessive pattern; most cases result from mutations in the SMN gene. Families with dominant and sex-linked inheritance have also been described.

The disease begins insidiously, with weakness and atrophy of the pelvic girdle and proximal leg muscles, followed by involvement of the shoulder girdle and upper arm muscles. Unlike the sporadic form of spinal muscular atrophy, the Wohlfart-Kugelberg-Welander variety (also listed in other books and monographs as Kugelberg-Welander disease) is bilaterally symmetrical from the beginning, and fasciculations are observed in only half the cases. Ultimately the distal limb muscles are involved and tendon reflexes are lost. Bulbar musculature and corticospinal tracts are spared, although Babinski signs and an associated ophthalmoplegia (presumably neural) have been reported in rare instances.

The presence of fasciculations and the EMG and muscle biopsy findings—all of which show the characteristic abnormalities of neural atrophy—permit distinction from muscular dystrophy. Cases that have been examined postmortem have shown loss and degeneration of the anterior horn cells.

The disease progresses very slowly, and some patients survive to old age without serious disability. In general, the earlier the onset, the less favorable the prognosis; however, even the most severely affected patients retain the ability to walk for at least 10 years after the onset. Admittedly, it is difficult to make a sharp distinction between these cases of Wohlfart-Kugelberg-Welander disease and certain milder instances of Werdnig-Hoffmann disease with onset in late infancy and early childhood and prolonged survival (Byers and Banker).

**Kennedy Syndrome (X-Linked Bulbospinal Muscular Atrophy)** An unusual pattern of **distal muscular atrophy with prominent bulbar signs** and, less often, ocular palsies was first described by Kennedy. The time of onset has varied from childhood to adult age, but most patients have been in their third decade when neurologic symptoms arose. Most cases have shown an X-linked pattern of inheritance and a lesser number an autosomal dominant pattern. The proximal shoulder and hip musculature are involved first by weakness and atrophy, followed in about half of patients by dysarthria and dysphagia. Often muscle cramps or twitching precede weakness. Facial fasciculations and mild weakness are also characteristic and may be striking. The tendon reflexes become depressed and may be absent; a mild sensory neuropathy is almost universal. In the family described by Kaeser, in which 12 members in five generations were affected, the pattern of weakness was shoulder-shank, i.e., scapuloperoneal; it may therefore be mistaken for muscular dystrophy. The muscular atrophy is associated in two-thirds of patients with gynecostasia, a feature that may first identify affected men in a kindred. Oligospermia and diabetes are frequent associations. The CK level is elevated, sometimes tenfold, and physiologic studies reveal denervation and reinnervation as well as indications of a mild sensory neuropathy.

As in Huntington disease and certain of the spinocerebellar atrophies, the genetic defect is a CAG expansion, in this case in the gene that codes for the androgen receptor on the short arm of the X chromosome (La Spada et al; see Table 39-7). Indeed, the first reported polyglutamine disease was in Kennedy syndrome. Lengthened sequences correlate with an earlier age of onset (anticipation, as in Huntington disease) but have no relation to the severity of disease. Androgen receptors have been found on motor neurons of the spinal cord; in fact, the subpopulation of motor neurons that is susceptible to both Kennedy syndrome and ALS express abundant surface androgen receptors, but it is not clear whether this has direct pathogenic significance. Neuronal inclusions have recently been described, composed of aggregations of the abnormally long polyglutamine protein sequences that correspond to the CAG expansion. A family with the bulbospinal phenotype but without the CAG expansion has also been reported (Paradiso et al). Other features, such as optic atrophy and sensory neuropathy, were present in some members of this kindred but are not features of typical cases. The diagnosis can be confirmed by genetic testing for the lengthened trinucleotide sequence. Prenatal diagnosis and identification of female carriers is also possible by genetic testing.

**Progressive Bulbar Palsy of Childhood (Fazio-Londe Syndrome)** Fazio in 1892 and Londe in 1893 described the development of a progressive bulbar palsy in children, adolescents, and young adults. There is progressive paralysis of the facial, lingual, pharyngeal, laryngeal, and sometimes ocular muscles. The illness usually presents with stridor and respiratory symptoms, followed by facial diplegia, dysarthria, dysphagia, and dysphonia. These become increasingly pronounced until the time of death some years later. In a few patients there is a late development of corticospinal signs and sometimes ocular palsies. Also jaw and oculomotor paresis appears occasionally, and in one case there was progressive deafness. The disease is rare, only 24 well-described examples having been recorded in the medical literature by 1992 (McShane et al). Inheritance may be autosomal dominant, as in Fazio’s original case, and rarely X-linked, but it is more likely to be autosomal recessive. Pathologic examination has shown a loss of motor neurons in the hypoglossal, ambiguous, facial, and trigeminal motor nuclei. In a few cases, the nerve cells in the ocular motor nuclei were also diminished. This disease, the few times we have encountered it, had to be differentiated from myasthenia gravis, a pontomedullary glioma, and brainstem multiple sclerosis.

**Hereditary Forms of Spastic Paraplegia**

**Hereditary Spastic Paraplegia (Strumpell-Lorrain Disease)** This disease was described by Seeligmuller in 1874 and later by Strümpell in Germany and Lorrain in France; it has now been identified in nearly every part of the world. The pattern of inheritance is usually autosomal dominant, less often recessive (one family has shown X-linked inheritance), and the onset may be at any age from childhood to the senium. Harding divided the disease into two groups, the more common one beginning before age 35 with a very protracted course and the other with a late onset (40 to 60 years). The latter type often shows sensory loss, urinary symptoms, and action tremor.

The clinical picture is that of a gradual development of spastic weakness of the legs with increasing difficulty in walking. The tendon reflexes are hyperactive and the plantar reflexes extensor. In the pure form of the disease, sensory and other nervous functions are entirely intact. If the onset is in childhood, as many cases are, the foot arches become exaggerated, the feet are shortened, and
there is a tightening (pseudocontracture) of calf muscles, forcing the child or adolescent to “toe-walk.” This is a common orthopedic problem and may require surgical correction. In children, the legs appear to be underdeveloped, and in both children and adults they may become quite thin. Sometimes the knees are slightly flexed; at other times the legs are fully extended or hyperextended (genu recurvatum) and adducted. Weakness is variable and difficult to estimate. Sphincteric function is usually retained. Subtle sensory loss in the feet has been reported. The arms are variably involved. In some patients, the arms appear to be spared even though the tendon reflexes are lively. In others, the hands are stiff, movements are clumsy, and speech is mildly dysarthric. Conjoined findings such as nystagmus, ocular palsies, optic atrophy, pigmentary macular degeneration, ataxia (both cerebellar and sensory), sensorimotor polynuropathy, ichthyosis, patchy skin pigmentation, epilysis, and dementia have all been described in isolated families (see further on).

The few available pathologic studies have shown that, in addition to degeneration of the corticospinal tracts throughout the spinal cord, there is thinning of the columns of Golli, mainly in the lumbosacral regions, and of the spinocerebellar tracts, even when no sensory abnormalities had been detected during life. These were the pathologic findings described by Strümpell in his original (1880) report of two brothers with spastic paraplegia; one of them, in addition, had a cerebellar syndrome, but again there were no sensory abnormalities. A reduction in the number of Betz and anterior horn cells has also been reported.

**Genetic Aspects of Hereditary Spastic Paraplegia** Several genetic mutations have given rise to this disease. As of this writing, there are 23 HSP loci (10 dominant, 9 recessive, 4 X-linked) and 11 HSP genes (see Table 39-8). The common uncomplicated autosomal dominant form of disease has been linked to chromosomes 2p, 8q, 14q, and 15q, the 2p variety being most frequent; the recessive variety has been linked to 8p, 15q (the most frequent recessive type), and 16q. Some of the recessive types have the unusual feature of thinning of the corpus callosum. The common variety associated with a mutation on chromosome 2p results in great variability of clinical presentation within and among families (see Nielsen and colleagues). Rare X-linked types have been associated with mutations on the long arm of the chromosome, one of which is an allelic variant of the Pelizaeus-Merzbacher gene.

In a few of these kindreds the genes responsible for disease have been identified. For example, the most common form is caused by mutations in the *spastin* gene, which encodes a membrane protein. Rarely, the causative mutation is in the metalloprotease gene *paraplegin* on the mitochondrial membrane; it is proposed that this defect impairs oxidative phosphorylation. The genetics of the hereditary spastic paraplegias has been reviewed by Fink.

**Differential Diagnosis** In the diagnosis of this disorder, one should consider an indolent spinal cord or foramemagnus tumor, cervical spondylitis, a spinal from of multiple sclerosis (this was the clinical diagnosis in Strümpell’s original cases), Chiari malformation, compression of the cord by a variety of congenital bony malformations at the craniocervical junction, and a number of chronic myelitides—among them, lupus erythematosus, sarcoidosis, acquired immunodeficiency syndrome (AIDS), adrenomyeloneuropathy, primary lateral sclerosis (described earlier in this chapter), and tropical spastic paraparesis (caused by HTLV-1).

**Variants of Familial Spastic Paraplegia** The literature contains a large number of descriptions of familial spastic paraplegia combined with other neurologic abnormalities. Some of the syndromes had developed early in life in conjunction with moderate degrees of mental retardation. In these, the rest of the neurologic picture appeared many years after birth and was progressive. Some idea of the number of these “hereditary paraplegia-plus” syndromes and the diverse combinations in which they may present is conveyed in the review by Gout and colleagues. Again, it is hardly possible to describe each of these symptoms in any degree of detail. The list below includes the best-known entities. But if the term hereditary spastic paraplegia is to have any neurologic significance, it should be applied only to the pure form of the progressive syndrome. The more common “atypical” or “syndromic” cases—with amyotrophy, cerebellar ataxia, tremors, dystonia, athetosis, optic atrophy, retinal degeneration, amnesia, and dementia—should be put in separate categories and their identity retained for nosologic purposes until such time as additional biochemical and genetic data related to pathogenesis are forthcoming. The gene mutations found in some of the variant types have been summarized by Fink, but—as with all types of uncomplicated hereditary spastic paraplegia—the mechanisms of neuronal loss are not known. To be separated from these cases are all the congenital nonprogressive types of

AD = autosomal dominant; AR = autosomal recessive; XR = X-linked
spastic diplegia and athetosis. The following list includes the best-known entities:

1. **Hereditary spastic paraplegia with spinocerebellar and ocular symptoms (Ferguson-Critchley syndrome).** This syndrome is characterized by a disorder of gaze, optic atrophy, cerebellar ataxia, and spastic paraparesis. Most impressive are the manifestations of spinocerebellar ataxia beginning during the fourth and fifth decades of life, accompanied by weakness of the legs, alterations of mood, pathologic crying and laughing, dysarthria and diplopia, dysesthesias of limbs, and poor bladder control. The tendon reflexes are lively, with bilateral Babinski signs. Sensation is diminished distally in the limbs. The whole picture resembles multiple sclerosis. In other cases, running through several generations of a family, the extrapyramidal features were more striking; such cases overlap with the following syndromes.

2. **Hereditary spastic paraplegia with extrapyramidal signs.** Action and static tremors, parkinsonian rigidity, dystonic tongue movement, and athetosis of the limbs have all been conjoined with spastic paraplegia. Gilman and Romanul have reviewed the literature on this subject. In the authors’ experience, the picture of parkinsonism with spastic weakness and other corticospinal signs has been the most frequent combination.

3. **Hereditary spastic paraplegia with optic atrophy.** This is known as Behr syndrome or optic atrophy-ataxia syndrome, since cerebellar signs are usually conjoined. Some of the members of the large family reported by Bruyn and Went also had athetosis. The syndrome is transmitted as an autosomal recessive trait, with onset in infancy and slow progression.

4. **Hereditary spastic paraplegia with macular degeneration (Kjellin syndrome).** Spastic paraplegia with amyotrophy, ophthalmoplegia, and central retinal degeneration constitutes the syndrome described in 1959 by Kjellin. While the mental retardation is stationary, the spastic weakness and retinal changes are of late onset and progressive. When ophthalmoplegia is added, it is called the Barnard-Scholz syndrome.

5. **Hereditary spastic paraplegia with mental retardation or dementia.** Many of the children with progressive spastic paraplegia either have been mentally retarded since early life or have appeared to regress mentally as other neurologic symptoms developed. Examples of this syndrome and its variants are too numerous to be considered here but are contained in the review of Gilman and Romanul. The autosomal recessive syndrome of Sjögren-Larsson, with the onset in infancy of spastic weakness of the legs in association with mental retardation, stands somewhat apart because of the associated ichthyosis.

6. **Hereditary spastic paraplegia with polyneuropathy.** We have observed several patients in whom a sensorimotor polyneuropathy was combined with unmistakable signs of corticospinal disease. The age of onset was in childhood or adolescence, and the disability progressed to the point where the patient was chair-bound by early adult life. In two of the cases, a sural nerve biopsy revealed a typical hypertrophic polyneuropathy; in a third case there was only a depletion of large myelinated fibers. The syndrome resembles the myeloneuropathy of adenoleukodystrophy.

7. **Spastic paraparesis with distal muscle wasting (Broyer syndrome).** This disorder is transmitted as an autosomal recessive trait. Onset is in childhood with amyotrophy of the hands, followed by spasticity and contractures of the lower limbs. Cerebellar signs (mild), athetosis, and deafness may be added.

### SYNDROME OF PROGRESSIVE BLINDNESS (See Chap. 13)

There are two main classes of progressive blindness in children, adolescents, and adults: progressive optic neuropathy and retinal degenerations (retinitis pigmentosa and so-called tapetoretinal macular degeneration). Of course, there are many congenital anomalies and retinal diseases beginning in infancy that result in blindness and microphthalmia. Some of those of neurologic interest have already been described briefly in connection with the hereditary spastic paraplegias and in Chap. 13.

### Hereditary Optic Atrophy of Leber

Although familial amaurosis was known in the early eighteenth century, it was Leber in 1871 who gave the definitive description of this disease and traced it through many genealogies. The family studies of Nikoskelainen and coworkers indicate that all daughters of carrier mothers become carriers themselves, a type of transmission that is determined by inheritance of defective mitochondrial DNA from the mother (Wallace et al). In an extensive review of Leber hereditary optic atrophy by the National Hospital group in London, some of the clinical variations are described. Common to all their cases was the presence of a pathogenic mitochondrial DNA abnormality (Riordan-Eva et al), but the defect may occur at one of several sites (page 841). Thus, Leber optic atrophy has been added to the growing list of mitochondrial diseases, which, as a group, are discussed in detail in Chap. 37.

In most patients, the visual loss begins between 18 and 25 years, but the range of age of onset is much broader. Usually the visual loss has an insidious onset and a subacute evolution, but it may evolve rapidly, suggesting a retrobulbar neuritis; moreover, in these latter instances, aching in the eye or brow may accompany the visual loss, just as it does in the demyelinating variety. Subjective visual phenomena are reported by some. Usually both eyes are affected simultaneously, though in some one eye is affected first, followed by the other after an interval of several weeks or months. In practically all cases, the second eye is affected within a year of the first. In the unimpaired eye, abnormalities of visual evoked potentials may antedate impairment of visual acuity (Carroll and Mastaglia).

Once started, the visual loss progresses over a period of weeks to months. Characteristically, central vision is lost before peripheral, and there is a stage at which bilateral central scotomata are readily demonstrable. Early on, perception of blue-yellow is deficient, while that of red and green is relatively preserved. In the more advanced stages, however, the patients are totally color-blind. Constriction of the fields may be added later. At first there may be swelling and hyperemia of the discs, but soon they become atrophic. Peripapillary vasculopathy, consisting of tortuosity and arteriovenous shunting, is the primary structural change; this has been present also in asymptomatic offspring of carrier females.

As visual symptoms develop, fluorescein angiography shows shunting in the abnormal vascular bed, with reduced filling of the capillaries of the papillomacular bundle. Although patients are left
with dense central scotomata, it is of some importance that the visual impairment is seldom complete; in some patients, relative stabilization of visual function occurs. In a few, there may be a surprising improvement.

Examination of the optic nerve lesion shows the central parts of the nerves to be degenerated from papillae to the lateral geniculate bodies, i.e., the papillomacular bundles are particularly affected. Presumably axis cylinders and myelin degenerate together, as would be expected from the loss of nerve cells in the superficial layer of the retina. Both astrocytic glial and endoneurial fibroblastic connective tissue are increased. Tests for the three main mitochondrial mutations that give rise to the disorder are now available.

Congenital optic atrophy (of which recessive and dominant forms are known), retrobulbar neuritis, and nutritional optic neuropathy are the main considerations in differential diagnosis.

**Retinitis Pigmentosa**

This remarkable retinal abiotrophy, known to Helmholtz in 1851 soon after he invented the ophthalmoscope, usually begins in childhood and adolescence. Unlike the optic atrophy of Leber, which affects only the third neuron of the visual neuronal chain, retinitis pigmentosa affects all the retinal layers, both the neuroepithelium and pigment layer to the superficial parts of the retina as the rod cells degenerate. The pigmentary change spares only the fovea, so that eventually the world is perceived by the patient as though he were looking through narrow tubes.

The many and diverse syndromes to which retinitis pigmentosa may be linked include: oligophrenia, obesity, syndactyly, and hypogonadism (Bardet-Biedl syndrome); hypogenitalism, obesity, and mental deficiency (Laurence-Moon syndrome); Friedreich and other types of spinocerebellar and cerebellar ataxia; spastic paraplegia and quadriplegia with Laurence-Moon syndrome; neurogenic amyotrophy, myopia, and color-blindness; polyneuropathy and deafness (Refsum disease); deaf mutism; Cockayne syndrome and Bassen-Kornzweig disease; and several mitochondrial diseases—particularly progressive external ophthalmoplegia and Kearns-Sayre syndromes.

The differential diagnosis includes the Batten form of cerebroretinal degeneration (ceroid lipofuscinosis), Pelizaeus-Merzbacher disease, and Gaucher disease as well as the various forms of ceroid lipofuscinosis and retinal infections such as syphilis, toxoplasmosis, and cytomegalic inclusion disease.

Virtual blindness is the outcome in many cases, but in others the visual failure stops short of that. It is doubtful whether any of the many proposed modes of therapy (sympathectomy, steroids, vitamins A and E, coenzyme Q10) have any effect in halting the progress of the disease.

**Stargardt Disease**

This is a bilaterally symmetrical, slowly progressive macular degeneration, differentiated from retinitis pigmentosa by Stargardt in 1909. In essence it is a hereditary (usually autosomal recessive) tapetoretinal degeneration or dystrophy (the latter term being preferred by Waardenburg), with onset between 6 and 20 years, rarely later, and leading to a loss of central vision. The macular region becomes gray or yellow-brown with pigmentary spots, and the visual fields show central scotomata. Later the periphery of the retina may become dystrophic. The lesion is well visualized by fluorescein angiography, which discloses a virtually pathognomonic “dark choroid” pattern. Activity in the electroretinogram is diminished or abolished. Both dominantly inherited Stargardt disease and the closely related cone-rod dystrophy have been linked to a defect on chromosome 6p in some families and 13q in others; the less common recessive variety has been mapped to 1p. In the former type, several gene errors code for a transporter protein (termed ABCR) of the photoreceptor.

This disease, with its selective loss of cone function, is in a sense the inverse of retinitis pigmentosa. According to Cohan and associates, it may be associated with epilepsy, Refsum syndrome, Kearns-Sayre syndrome, Bassen-Kornzweig syndrome, or Sjögren-Larsson syndrome, or with spinocerebellar and other forms of cerebellar degeneration and familial paraplegia.

**SYNDROME OF PROGRESSIVE DEAFNESS** (See Chap. 15)

There is an impressive group of hereditary, progressive cochleo-vestibular atrophies that are linked to degenerations of the nervous system. These are the subject of an informative review by Konigsmark and are summarized below. Such neuro-otologic syndromes must be set alongside a group of five diseases that affect the auditory and vestibular nerves exclusively: dominant progressive nerve deafness; dominant low-frequency hearing loss; dominant midfrequency hearing loss; sex-linked, early-onset neural deafness; and hereditary episodic vertigo and hearing loss. The last of these is of special interest to neurologists because both balance and hearing are affected.
It should be pointed out that in 70 percent of cases of hereditary deafness, there are no other somatic or neurologic abnormalities. To date, three separate autosomal mutations have been identified that are associated with this pure “nonsyndromic” type of hereditary deafness, the most common of which is in the connexin gene as discussed in Chap. 15. In one such family from Costa Rica, the gene codes for a protein that regulates the polymerization of actin, the major cytoskeletal component of the hair cells of the inner ear (see review by Pennisi). More recently, a number of mitochondrial disorders have been associated with deafness alone as well as with a number of the better-characterized mitochondrial syndromes (see Chap. 37). The age of onset of hearing loss in the pure forms has been variable, extending well into adulthood.

Hereditary Hearing Loss with Retinal Diseases Konigsmark has separated this overall category into three subgroups: patients with typical retinitis pigmentosa, those with Leber optic atrophy, and those with other retinal changes.

With respect to retinitis pigmentosa, four syndromes are recognized in which retinitis pigmentosa appears in combination: with congenital hearing loss (Usher syndrome); with polyneuropathy (Refsum syndrome); with hypogonadism and obesity (Alstrom syndrome); and with dwarfism, mental retardation, premature senility, and photosensitive dermatitis (Cockayne syndrome).

Hereditary hearing loss with optic atrophy forms the core of four special syndromes: dominant optic atrophy, ataxia, muscle wasting, and progressive hearing loss (Sylvester disease); recessive optic atrophy, polyneuropathy, and neural hearing loss (Rosenberg-Chutorian syndrome); optic atrophy, hearing loss, and juvenile diabetes mellitus (Tunbridge-Paley syndrome); and optocerebrodentate degeneration with optic atrophy, hearing loss, quadriaparesis, and mental retardation (Nyssen–van Bogaert syndrome).

Hearing loss has also been observed with other retinal changes, two of which might be mentioned here: Norrie disease, with retinal malformation, hearing loss, and mental retardation (oculocauicostocerebral degeneration), and Small disease, with recessive hearing loss, mental retardation, narrowing of retinal vessels, and muscle atrophy. In the former, the infant is born blind, with a white vascularized retinal mass behind a clear lens; later the lens and cornea become opaque. The eyes are small and the iris is atrophied. In the latter, the optic fundi show tortuosity of vessels, telangiectases, and retinal detachment. The nature of the progressive generalized muscular weakness has not been ascertained.

Hereditary Hearing Loss with Diseases of the Nervous System There are several conditions in which hereditary deafness accompanies degenerative disease of the peripheral or central nervous system. Those associated with mitochondrial encephalopathies have already been mentioned. The other main types with autosomal inheritance include the following:

1. Hereditary hearing loss with epilepsy. The seizure disorder is mainly one of myoclonus. In one dominantly inherited form, photomyoclonus is associated with mental deterioration, hearing loss, and nephropathy (Hermann disease). In May–White disease, also inherited as an autosomal dominant trait, myoclonus and ataxia accompany hearing loss. Congenital deafness and mild chronic epilepsy of recessive type have also been observed (Latham-Monro disease).

2. Hereditary hearing loss and ataxia. Here Konigsmark was able to delineate five syndromes, the first two of which show a dominant pattern of heredity, the last three a recessive pattern: piebaldism, ataxia, and neural hearing loss (Tellf syndrome); hearing loss, hyperuricemia, and ataxia (Rosenberg-Bergstrom syndrome); ataxia and progressive hearing loss (Lichtenstein-Knorr syndrome); ataxia, hypogonadism, mental deficiency, and hearing loss (Richards-Rundle syndrome); ataxia, mental retardation, hearing loss, and pigmentary changes in the skin (Jeune-Tommasi syndrome).

3. Hereditary hearing loss and other neurologic syndromes (see Table 15-1). These include dominantly inherited sensory radicular neuropathy (Denny-Brown); progressive polyneuropathy, kypchoscoliosis, skin atrophy, eye defects (myopia, cataracts, atypical retinitis pigmentosa), bone cysts, and osteoporosis (Flynn-Aird syndrome); chronic polyneuropathy and nephritis (Lemieux-Neemeh syndrome); congenital pain asymologia and auditory imperception (Osuntokun syndrome); and bulbopontine paralysis (facial weakness, dysarthria, dysphagia, and atrophy of the tongue with fasciculations) with progressive neural hearing loss. The onset of the last syndrome occurs at 10 to 35 years of age; the pattern of inheritance is autosomal recessive. The disease progresses to death. It resembles the progressive hereditary bulbar paralysis of Fazio-Londe except for the progressive deafness and loss of vestibular responses. Regrettably, in most of these syndromes, there are no data regarding labyrinthine function.

The details of these many syndromes are contained in Konigsmark’s review. The main syndromes are listed in Table 15-1 (page 254) and have been summarized here in order to increase awareness of the large number of hereditary-degenerative neurologic diseases for which the clue is provided by the detection of impaired hearing and labyrinthine functions.

CHAPTER 39 DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM

CHAPTER 40

THE ACQUIRED METABOLIC DISORDERS OF THE NERVOUS SYSTEM

An important segment of neurologic medicine and one that is seen with great frequency in general hospitals consists of disorders in which a global disturbance of cerebral function (encephalopathy) results from failure of some other organ system—heart and circulation, lungs and respiration, kidneys, liver, pancreas, and the endocrine glands. Unlike the diseases considered in Chap. 37, in which a genetic abnormality affects the metabolic functions of many organs and tissues, including the brain, the cerebral disorders discussed in this chapter are strictly secondary to derangements of the visceral organs themselves. They stand at the interface of internal medicine and neurology.

Relationships of this type, between an acquired disease of some thoracic, abdominal, or endocrine organ and the brain, have rather interesting implications. In the first place, recognition of the neurologic syndrome may be a guide to the diagnosis of the systemic disease; indeed, the neurologic symptoms may be more informative and significant than the symptoms referable to the organ primarily involved. Moreover, these encephalopathies are often reversible if the systemic dysfunction is brought under control. Neurologists must therefore have an understanding of the underlying medical disorder, for this may provide the means of controlling the neurologic part of the disease. In other words, the therapy for what appears to be a neurologic disease lies squarely in the field of internal medicine—a clear reason why every neurologist should be well trained in internal medicine. Of more theoretical importance, the investigation of the acquired metabolic diseases may provide new insights into the chemistry and pathology of the brain. To select a single example, the discovery of an episodic encephalopathy that is associated with advanced liver disease and portocaval shunts opened a vast new area in brain chemistry, pertaining to the effect of ammonia on glutamine metabolism, and has brought to light an intriguing histopathologic change—a relatively pure hyperplasia of protoplasmic astrocytes. Each visceral disease affects the brain in a somewhat different way, and since the pathogenic mechanism is not completely understood in any of them, the study of these metabolic diseases promises rich rewards to the scientist.

In Table 40-1 the acquired metabolic diseases of the nervous system are classified according to their most common modes of clinical expression. Not included are the diseases due to nutritional deficiencies and those due to exogenous drugs and toxins, which can be considered metabolic in the broad sense; these are presented in the following chapters.

METABOLIC DISEASES PRESENTING AS A SYNDROME OF CONFUSION, STUPOR, OR COMA

The syndrome of impaired consciousness, its general features, the terms used to describe it, and the mechanisms involved are discussed in Chap. 17, which serves as an introduction to this section. There it is pointed out that metabolic disturbances are frequent causes of impaired consciousness and that their presence must always be considered when there are no focal signs of cerebral disease and both the imaging studies and the cerebrospinal fluid (CSF) are normal. Intoxication with alcohol and other drugs figures prominently in the differential diagnosis. The main features of the reversible metabolic encephalopathies are mental confusion, typified by disorientation and inattentiveness and accompanied in certain special instances by asterixis, tremor, and myoclonus, but usually without signs of focal cerebral disease. This state may progress in stages to one of stupor and coma. Slowing of the background rhythms in the electroencephalogram (EEG) reflects the severity of the metabolic disturbance. With few exceptions, usually pertaining to cerebral edema, imaging studies are normal.

Laboratory examinations are highly informative in the investigation of the acquired metabolic diseases. In every patient with symptoms suggestive of a metabolic encephalopathy, the following determinations should be made: serum Na, K, Ca, glucose, BUN, NH₃, and osmolality. If there is evidence of hypoxia or the patient is known to have chronic obstructive airway disease, determination of arterial pH, PCO₂, and PO₂ are carried out as well. Serum osmolality can be measured directly or calculated from the values of Na (meq/L, K meq/L), glucose, and BUN (in mg/dL), using the following formula:

\[
\text{Serum osmolality} = 2[(\text{Na}) + (\text{K})] + \text{glucose/18} + \text{BUN/3}
\]

When there is a discrepancy between the calculated and the directly measured osmolalities, it can be assumed that additional circulating ions are present. Most often they are derived from an exogenous toxin or drug such as mannitol, but renal failure, ketoacidemia, and an increase of serum lactate may also result in the accumulation of small molecules that contribute to the serum osmolality.

Where an exogenous toxin is suspected of causing an encephalopathy and in all cases where the cause is unknown, a “toxic screen” of blood and urine, using high-pressure liquid chromatography, should be obtained. A point to be remembered is that the brain may be damaged, even to an irreparable degree, by a disturbance of blood chemistry (e.g., hypoglycemia, hypoxia) that has vanished by the time the patient is examined.

Ischemic-Hypoxic (Ischemic-Anoxic) Encephalopathy

Here the basic disorder is a lack of oxygen and of blood flow to the brain, the result of failure of the heart and circulation or of the lungs and respiration. Often both mechanisms and both organ failures are responsible and one cannot say which predominates; hence the dually ambiguous allusions in medical records to “cardiores-

When blood flow is stable, the most important element in the delivery of oxygen is the oxygen content of the blood. This is the product of hemoglobin concentration and the percentage of oxygen saturation of the hemoglobin molecule. At normal temperature and pH, hemoglobin is 90% saturated at an oxygen partial pressure of 60 mmHg and still 75% saturated at 40 mmHg; i.e., as is well known, the oxygen saturation curve is not linear. The product of the oxygen content and the cardiac output is the ultimate determinant of the adequacy of oxygen supply to the organs.

Reduced to the simplest formulation, a deficient supply of oxygen to the brain is due either to a failure of cerebral perfusion (ischemia) or to a reduced amount of circulating arterial oxygen, the result of diminished oxygen saturation, or insufficiency of hemoglobin (hypoxia). Although they are often combined, the neurologic effects of ischemia and hypoxia are subtly different.

**Physiology of Ischemic and Hypoxic Damage**

A number of physiologic mechanisms of a homeostatic nature protect the brain under conditions of both ischemia and hypoxia. Through a mechanism termed *autoregulation*, there is a compensatory dilatation of resistance vessels in response to a reduction in cerebral perfusion, which maintains blood flow at a constant rate, as noted in Chap. 34. When the cerebral blood pressure falls below 60 to 70 mmHg, an additional compensation in the form of increased oxygen extraction allows normal energy metabolism to continue. In total cerebral ischemia, the tissue is depleted of its sources of energy in about 5 min, although longer periods are tolerated under conditions of hypothermia. Also, energy failure due to hypoxia is counteracted by an autoregulatory increase in cerebral blood flow; at a Po2 of 25 mmHg, the increase in blood flow is approximately 400 percent. A similar increase in flow occurs with a decrease in hemoglobin to 20 percent of normal.

In most clinical situations in which the brain is deprived of adequate oxygen, as already commented, there is a combination of ischemia and hypoxia, with one or the other predominating. The pathologic effects of ischemic brain injury from systemic hypotension differ from those due to pure anoxia. Under conditions of ischemia, the main damage takes the form of incomplete infarctions in the border zones between major cerebral arteries. With anoxia, neurons in portions of the hippocampus and the deep folia of the cerebellum are particularly vulnerable. More severe degrees of either ischemia or hypoxia lead to selective damage to certain layers of cortical neurons, and if more profound, to generalized damage of all the cerebral cortex, deep nuclei, and cerebellum. The nuclear structures of the brainstem and spinal cord are relatively resistant to anoxia and hypotension and stop functioning only after the cortex has been badly damaged.

The cellular pathophysiology of neuronal damage under conditions of ischemia is discussed in Chap. 34. Essentially, the mechanism of injury is an arrest of the aerobic metabolic processes necessary to sustain the Krebs (tricarboxylic acid) cycle and the electron transport system. Neurons, if completely deprived of their source of energy, proceed to catabolize themselves in an attempt to maintain their activity and in so doing are damaged to a degree that does not permit their survival—i.e., they undergo necrosis. The accumulation of catabolic products (particularly lactic acid) in the interstitial tissue contributes to the parenchymal damage. Ultimately, the accumulated injury leads to cell death, probably through more than one mechanism. The most acute forms of cell death are characterized by massive swelling and necrosis of neuronal and nonneuronal cells (cytotoxic edema). Short of immediate
ischemic necrosis, a series of internally programmed cellular events may also propel the cell toward death in a delayed fashion, a process for which the term apoptosis has been borrowed from embryology. There is experimental evidence that certain excitatory neurotransmitters, particularly glutamate, contribute to the rapid destruction of neurons under conditions of anoxia and ischemia (Choi and Rothman); the pertinence of these effects to clinical situations is uncertain. Ultimately, this process may be affected by massive calcium influx through a number of different membrane channels, which activates various kinases that participate in the process of gradual cellular destruction. There is also a poorly understood phenomenon of delayed neurologic deterioration after anoxia; this may be due to the blockage or exhaustion of some enzymatic process during the period when brain metabolism is restored.

Clinical Features of Anoxic Encephalopathy  Mild degrees of hypoxia without loss of consciousness induce only inattentiveness, poor judgment, and motor incoordination; in our experience there have been no lasting clinical effects in such cases, though Hornbein and colleagues found, on psychologic testing, a slight decline in visual and verbal long-term memory and mild aphasic errors in Himalayan mountaineers who had earlier ascended to altitudes of 18,000 to 29,000 ft. These observations make the point that profound anoxia may be well tolerated if arrived at gradually. For example, we have seen several patients with advanced pulmonary disease who were fully awake when their arterial oxygen pressure was in the range of 30 mmHg. This level, if it occurs abruptly, causes coma. An important derivative rule is that degrees of hypoxia that at no time abolish consciousness rarely if ever cause permanent damage to the nervous system.

In the circumstances of severe global ischemia with prolonged loss of consciousness, the clinical effects can be quite variable. Following cardiac arrest, for example, consciousness is lost within seconds, but recovery will be complete if breathing, oxygenation of blood, and cardiac action are restored within 3 to 5 min. Beyond 5 min there is usually permanent injury. As shown in experimental models, one of the reasons for the irreversibility of the lesion may be swelling of the endothelium and blockage of circulation into the ischemic cerebral tissues, the so-called no-reflow phenomenon described by Ames and colleagues. Clinically, however, it is often difficult to judge the precise degree and duration of ischemia, since slight heart action or an imperceptible blood pressure may have served to maintain the circulation to some extent. Hence some individuals have made an excellent recovery after cerebral ischemia that apparently lasted 8 to 10 min or longer. Subnormal body temperatures, as might occur when the body is immersed in ice-cold water, greatly prolong the tolerable period of hypoxia. This has led to the successful application of moderate cooling after cardiac arrest as a technique to limit cerebral damage (see further on).

Generally speaking, anoxic patients who demonstrate intact brainstem function—as indicated by normal pupillary light and ciliospinal responses, “doll’s-head” eye movements, and ocucLovestibular reflexes—have a more favorable outlook for recovery of consciousness and perhaps all of their faculties. Conversely, the absence of these brainstem reflexes even after circulation and oxygenation have been restored, particularly pupils that are unchanged to light, implies a grave outlook in most circumstances, as elaborated further on. If the damage is almost total, coma persists, decerebrate postures may be present spontaneously or in response to painful stimuli, and bilateral Babinski signs can be evoked. In the first 24 to 48 h, death may terminate this state in a setting of rising temperature, deepening coma, and circulatory collapse, or the syndrome of brain death intervenes, as discussed below.

Most patients who have suffered severe but lesser degrees of hypoxia will have stabilized their breathing and cardiac activity by the time they are first examined; yet they may be comatose, with the eyes slightly divergent and motionless but with reactive pupils, the limbs inert and flaccid or intensely rigid, and the tendon reflexes diminished. Within a few minutes after cardiac action and breathing have been restored, generalized convulsions and isolated or grouped myoclonic twitches of muscles may supervene. The seizures, if severe and recurrent, double or treble the oxygen need of cerebral tissues. With severe degrees of injury, the cerebral and cerebellar cortices and parts of the thalami are partly or completely destroyed but the brainstem-spinal structures survive. Tragically, the individual may survive for an indefinite period in a state that is variously referred to as cortical death, irreversible coma, or persistent vegetative state (see page 304).

Some patients remain mute, unresponsive, and unaware of their environment for weeks, months, or years. Long survival is usually attended by some degree of improvement, but the patient appears to know nothing of his present situation and to have lost all past memories, power of reasoning, and capacity for meaningful social interaction and independent existence (a so-called minimally responsive state, actually a severe dementia, page 305). One has only to observe such patients and their families to appreciate the gravity of the problem, the family’s anguish, and the tremendous expense of medical care. The only person who does not appear to suffer is the patient.

With lesser degrees of anoxic-ischemic injury, the patient improves after a period of coma lasting hours or less. Some of these patients quickly pass through this acute posthypoxic phase and proceed to make a full recovery; others are left with varying degrees of permanent disability.

The findings on imaging studies vary. The most common early change in cases of severe injury is a loss of the distinction between the cerebral gray and white matter (Fig. 40-1); both ischemia and hypoxia are usually involved. Patient with this finding are invariably comatose and few awaken with a good neurologic outcome. With less severe and predominantly hypotensive-ischemic events such as cardiac arrest, watershed infarctions become evident in the border zones between the anterior, middle, and posterior cerebral arteries (Fig. 40-2). The clinical syndromes associated with watershed infarction are discussed below.

Brain Death Syndrome (See Chap. 17) This represents the most severe degree of oxygen lack, usually caused by circulatory arrest; it is manifest by a state of complete unawareness and unresponsiveness with abolition of all brainstem reflexes. Natural respiration cannot be sustained; only cardiac action and blood pressure are maintained. No electrical activity is seen in the EEG (it is isoelectric). At autopsy one finds that most if not all the gray matter of cerebral, cerebellar, and brainstem structures—and in some instances even the upper cervical spinal cord—has been severely damaged.

One must always exercise caution in concluding that a patient has this form of irreversible brain damage, because anesthesia, intoxication with certain drugs, and hypothermia may also cause deep coma and an isoelectric EEG but permit recovery. Therefore it is often advisable to repeat the clinical and laboratory tests after an interval of a day or so, during which time the results of toxic screen-
The two watershed syndromes rarely coexist. The interested reader may consult the appropriate chapter in the text on neurologic intensive care by Ropper and associates for further details.

Seizures may or may not be a problem, and they are often resistant to treatment. Well-formed motor convulsions are infrequent. Myoclonus is more common and may be intermixed with fragmentary convulsions. Myoclonus is a grave sign in most cases, but it generally recedes after several hours or a few days. These movements are also difficult to suppress, as noted further on.

Delayed Postanoxic Encephalopathy  This is a relatively uncommon and unexplained phenomenon. Initial improvement, which appears to be complete, is followed after a variable period of time (1 to 4 weeks in most instances) by a relapse, characterized by apathy, confusion, irritability, and occasionally agitation or mania. Most patients survive this second episode, but some are left with serious mental and motor disturbances (Choi; Plum et al). In still other cases, there appears to be progression of the initial neurologic syndrome with additional weakness, shuffling gait, diffuse rigidity and spasticity, sphincteric incontinence, coma, and death after 1 to 2 weeks. Exceptionally, there is yet another syndrome in which an episode of hypoxia is followed by slow deterioration, which progresses for weeks to months until the patient is mute, rigid, and helpless. In such cases the basal ganglia are affected more than the cerebral cortex and white matter as in the case studied by our colleagues Dooling and Richardson. Instances have followed cardiac arrest, drowning, asphyxiation, and carbon monoxide poisoning.

Posthypoxic Neurologic Syndromes  The permanent neurologic sequelae or posthypoxic syndromes observed most frequently are as follows:

1. Persistent coma or stupor, described above
2. With lesser degrees of cerebral injury, dementia with or without extrapyramidal signs
3. Extrapyramidal (parkinsonian) syndrome with cognitive impairment (discussed in relation to carbon monoxide poisoning)
4. Choreoathetosis
5. Cerebellar ataxia
6. Intention or action myoclonus
7. A Korsakoff amnesic state

If ischemic hypoperfusion dominates, the patient may also display the manifestations of watershed infarctions, situated between the end territories of the major cerebral vessels. The main syndromes that become evident soon after the patient awakens are:

1. Visual agnosias including Balint syndrome and cortical blindness (page 406), representing infarctions of the watershed between the middle and posterior cerebral arteries (Fig. 40-2)
2. Proximal arm and shoulder weakness, sometimes accompa-
**Prognosis of Hypoxic-Ischemic Brain Injury** Several logistic models have been developed to predict the outcome of anoxic-ischemic coma. All of them incorporate several simple clinical features involving loss of motor, verbal, and pupillary functions in various combinations. The most often cited and extensive study of the prognostic aspects of coma following cardiac arrest is the one by Levy and colleagues of 150 patients who remained in coma for at least 6 h after cardiac arrest. It has provided the following guidelines: mortality from this state is high: 20 percent died on the first day and 64 percent by the end of 1 week. In terms of recovery, 17 percent of the patients who awakened had done so by 3 days, and only an additional 2 percent did so by 2 days. At the other extreme of the 31 percent of patients who were in a vegetative state at 1 day, 70 percent survived for 1 week, and only 3 patients recovered. Further details pertaining to prognosis are to be found in Chap. 17, “Coma and Related Disorders of Consciousness.”

Once intoxication is excluded, the presence of fixed, dilated pupils and paralysis of eye movement for 24 to 48 h, along with absence of motor responses to painful stimuli, signify irreversible cerebral damage. We have never observed deep coma of this type lasting 5 days in an adult or more to be attended by full recovery. The question of what to do with patients in such states of protracted coma is a societal as much as a medical problem. The most that can be expected of the neurologist is to state the level and degree of brain damage, its cause, and the prognosis based on his own and published experience. One prudently avoids heroic, lifesaving therapeutic measures once the nature of this state has been determined with certainty.

**Treatment of Hypoxic-Ischemic Encephalopathy** Treatment is directed initially to the prevention of further hypoxic injury. As a clear airway is secured, the use of cardiopulmonary resuscitation, a cardiac defibrillator, or pacemaker has its place, and every second counts in their prompt utilization. Once cardiac and pulmonary function are restored, there is experimental and clinical evidence that reducing cerebral metabolic requirements by hypothermia has a slight beneficial effect on outcome and may also prevent the delayed worsening referred to above. The use of barbiturates has not met with the same success. Particular attention is drawn to the randomized trial conducted by Bernard and colleagues of mild hypothermia applied to unconscious patients immediately after cardiac arrest. They reduced the core temperature of affected patients to 33°C (91°F) within 2 h and demonstrated a doubling of the rate of survival and good outcome. These effects were evaluated by coarse measures of neurologic function, and these findings have been corroborated in the smaller trial reported by Zeiner et al. Vasodilator drugs, glutamate blockers, and calcium channel blockers are of no proven benefit despite their theoretical appeal and some experimental successes. Oxygen may be of value during the first hours but is probably of little use after the blood becomes well oxygenated. Corticosteroids ostensibly help to allay brain (possibly cellular) swelling, but again, their therapeutic benefit has not been corroborated by clinical trials.

Seizures should be controlled by the methods indicated in Chap. 16. If they are severe, continuous, and unresponsive to the usual anticonvulsant drugs, controlled respiration, continuous infusion of a drug such as midazolam, and eventually the suppression of their convulsive aspect with neuromuscular blocking agents may be required. Often the seizures cease after a few hours and are replaced by polymyoclonus. For the latter, clonazepam, 8 to 12 mg daily in divided doses may be useful, but the commonly used anticonvulsants have little effect in our experience. This state of spontaneous and stimulus-sensitive myoclonus as well as persistent limb posturing usually presages a poor outcome. The striking disorder of delayed movement-induced myoclonus and ataxic tremor that appear after the patient awakens, described by Lance and Adams, is a special issue, discussed on page 89. Its treatment requires the use of multiple medications. Fever is treated with antipyretics or a cooling blanket combined with neuromuscular paralyzing agents.

**Carbon Monoxide Poisoning**

Strictly speaking, carbon monoxide (CO) is an exogenous toxin, but it is considered here because it produces a unique anoxia and one that is frequently associated with delayed neurologic deterioration. The extreme affinity of CO for hemoglobin (over 200 times that of oxygen) drastically reduces the oxygen content of blood and subjects the brain to prolonged hypoxia and acidosis. Cardiac toxicity and hypotension generally follow. Whether CO also has a direct toxic action on neuronal components is not settled. The effects on the brain for the most part simulate those caused by cardiac arrest. Neurologists are likely to encounter instances of CO poisoning in burn units and in patients who have attempted suicide or have been exposed accidentally to a faulty furnace or to car exhaust in a closed garage.

Early symptoms include headache, nausea, dyspnea, confusion, dizziness, and clumsiness. These occur when the carboxyhemoglobin level reaches 20 to 30 percent of total hemoglobin. Exposure to relatively low levels of CO from faulty furnaces and gasoline engines should be suspected as the cause of recurrent headaches and confusion that clear upon hospitalization or other change of venue. A cherry-red color of the skin may appear but is actually an infrequent finding; cyanosis is more common. At slightly higher levels of carboxyhemoglobin, blindness, visual field defects, and papilledema develop, and levels of 50 to 60 percent are associated with coma, decerebrate or decorticate posturing, seizures in a few patients, and generalized slowing of the EEG rhythms. The initial computed tomography (CT) scanning is normal or shows mild cerebral edema; later scans may show a characteristic lesion in the pallidum, as described below. Only if there has been associated hypotension does one see the same types of border-zone infarctions that appear after cardiac arrest.

Delayed neurologic deterioration 1 to 3 weeks (sometimes much longer) after CO exposure occurs more frequently than with other forms of cerebral hypoxia. In Choi’s survey, this feature was observed in 3 percent of 2360 cases of CO poisoning and in 12 percent of those ill enough to be admitted to a hospital. Extrapyramidal features (parkinsonian gait and bradykinesia) predominated. Three-quarters of such patients were said to recover within a year. Discrete lesions centered in the globus pallidus bilaterally and sometimes the inner portion of the putamina are characteristic of CO poisoning that had produced coma (Fig. 40-3), but similar focal destruction may be seen after drowning, strangulation, and other forms of anoxia. The common feature among the delayed-relapse patients is a prolonged period of pure anoxia (before the occurrence of ischemia). Basal ganglial lesions may be quite prominent on CT scans even when delayed neurologic sequelae do not occur, but they are invariably present between 1 and 4 weeks in patients who develop a delayed extrapyramidal syndrome. In less severely affected patients, we have seen such lesions on CT and magnetic resonance imaging (MRI) resolve entirely.
The treatments for altitude illness are reviewed by Hackett and Roach.

*Chronic mountain sickness*, sometimes called Monge disease (after the physician who described the condition in Andean Indians of Peru), is observed in long-term inhabitants of high-altitude mountainous regions. Pulmonary hypertension, cor pulmonale, and secondary polycythemia are the main features. There is usually hypercarbia as well, with the expected degree of mild mental dullness, slowness, fatigue, nocturnal headache, and sometimes papilledema (see below). Thomas and colleagues have called attention to a syndrome of burning hands and feet in these groups of Peruvians, apparently another maladaptive response to high altitude.

Sedatives, alcohol, and a slightly elevated PCO₂ in the blood all reduce one’s tolerance to high altitude. Dexamethasone and acetazolamide prevent and counteract mountain sickness to some extent. The most effective preventive measure is acclimatization by a 2- to 4-day stay at intermediate altitudes of 6000 to 8000 ft.

**Hypercapnic Pulmonary Disease**

Chronic obstructive pulmonary disease such as emphysema, fibrosing lung disease, neuromuscular weakness, and in some instances an inadequacy of the medullary respiratory centers each may lead to persistent respiratory acidosis, with elevated of PCO₂ and reduced in arterial Po₂. The complete clinical syndrome of chronic hypercapnia described by Austen, Carmichael, and Adams comprises headache, papilledema, mental dullness, drowsiness, confusion, stupor and coma, and asterixis. More typically, only some of these features are found. Some patients have a fast-frequency tremor. The headache tends to be generalized, frontal, or occipital and can be quite intense, persistent, steady, and aching in type; nocturnal occurrence is a feature of some cases. The papilledema is bilateral but may be slightly greater in one eye than in the other, and hemorrhages may encircle the choked disc (a later finding). Visual acuity is undiminished and the visual fields are full. The tendon reflexes are lively and plantar reflexes may be extensor. Intermittent drowsiness, indifference to the environment, inattentiveness, reduction of psychomotor activity, inability to perceive all the items in a sequence of events, and forgetfulness constitute the more subtle manifestations of this syndrome and may prompt the family to seek medical help. Such symptoms may last only a few minutes or hours, and one cannot count on their presence at the time of a particular examination. In fully developed cases, the CSF is under increased pressure; PCO₂ may exceed 75 mmHg, and the O₂ saturation of arterial blood ranges from 85 percent to as low as 40 percent. The EEG shows slow activity in the delta or theta range, which is sometimes bilaterally synchronous.

The mechanism of the cerebral disorder is said to be a direct CO₂ narcosis, but the biochemical details are not known. Normally the CSF is slightly acidic in comparison to the blood, and the PCO₂ of the CSF is about 10 mmHg higher than that of the blood. With respiratory acidosis, the pH of the CSF falls (into the range of 7.15 to 7.25) and cerebral blood flow increases as a result of cerebral vasodilatation. However, the brain rapidly adapts to respiratory acidosis through the generation and secretion of bicarbonate by the choroid plexuses. Brain water content also increases, mainly in the white matter. In animal models of hypercarbia, blood and brain NH₃ is elevated, which may explain the similarity of the syndrome to that of hyperammonemic liver failure (Herrera and Kazemi).

The most effective therapeutic measures are ventilation with

**High-Altitude (Mountain) Sickness**

*Acute mountain sickness* is another special form of cerebral hypoxia. It occurs when a sea-level inhabitant abruptly ascends to a high altitude. Headache, anorexia, nausea and vomiting, weakness, and insomnia appear at altitudes above 8000 ft; on reaching higher altitudes, there may be ataxia, tremor, drowsiness, mild confusion and hallucinations. At 16,000 ft, according to Griggs and Sutton, 50 percent of individuals develop asymptomatic retinal hemorrhages, and it has been suggested that such hemorrhages also occur in the cerebral white matter. Extreme altitude sickness may result in fatal cerebral edema. The overexpression of vascular endothelial growth factor (VEGF), a protein originally noted for its effects on vascular permeability, has been implicated as the cause of cerebral edema in the experiments of Schoch and colleagues. With more prolonged exposure at these altitudes or with further ascent, affected individuals suffer mental impairment that may progress to coma. Hypoxemia at high altitude is intensified during sleep, as ventilation normally diminishes. Reference was made earlier to the observation of Hornbein and colleagues of a mild but possibly lasting memory impairment in even acclimated mountaineers who have been exposed to extremely high altitudes for several days.

Initial treatment is with inspired oxygen. Because the half-life of CO (normally 5 hours) is greatly reduced by the administration of hyperbaric oxygen at 2 or 3 atmospheres, this treatment is recommended when the carboxyhemoglobin concentration is greater than 40 percent or in the presence of coma or seizures (Myers et al). This treatment reduces the incidence of cognitive sequelae from 46 to 25 percent according to a trial conducted by Weaver and colleagues. They administered three hyperbaric sessions in the first 24 h after exposure to CO.

**Figure 40-3.** Unenhanced CT scan of the brain of a 30-year-old woman who attempted suicide by carbon monoxide inhalation. The only neurologic residua were a mild defect in retentive memory and areas of decreased attenuation in the pallidum bilaterally (arrows).
a positive-pressure device, using oxygen if there is hypoxia. Oxygen supplementation is, of course, used cautiously in these patients in order to avoid suppressing respiratory drive—marginally compensated patients treated with excessive oxygen have lapsed into coma. Treatment of heart failure, phlebotomy to reduce the viscosity of the blood, and antibiotics to suppress pulmonary infection may be necessary. Often these measures result in a surprising degree of improvement, which may be maintained for months or years.

Unlike pure hypoxic encephalopathy, prolonged coma due to hypercapnia is relatively rare and in our experience has not led to irreversible brain damage. Papilledema and jerky, intermittent lapses of sustained muscular contraction (asterixis) are important diagnostic features. If aminophylline is administered for the treatment of the underlying pulmonary airway disease, there may be a tendency for seizures. The syndrome is apt to be mistaken for a brain tumor, confusional psychosis of other type, or a disease causing chorea or myoclonus. In the last instance, hypercapnia must be distinguished from other metabolic diseases presenting as chronic extrapyramidal syndromes, as described later in this chapter.

**Hypoglycemic Encephalopathy**

This condition is now relatively infrequent but is an important cause of confusion, convulsions, stupor, and coma; as such, it merits separate consideration as a metabolic disorder of the brain. The essential biochemical abnormality is a critical lowering of the blood glucose. At a level of about 30 mg/dL, the cerebral disorder takes the form of a confusional state, and one or more seizures may occur; at a level of 10 mg/dL, there is profound coma that may result in irreparable injury to the brain if not corrected immediately by the administration of glucose. As with most other metabolic encephalopathies, the rate of decline of blood glucose is a factor.

The normal brain has a glucose reserve of 1 to 2 g (30 mmol per 100 g of tissue), mostly in the form of glycogen. Since glucose is utilized by the brain at a rate of 60 to 80 mg/min, the glucose reserve will sustain cerebral activity for only about 30 min once blood glucose is no longer available. Glucose is transported from the blood to the brain by an active carrier system. Glucose entering the brain either undergoes glycolysis or is stored as glycogen. During normal oxygenation (aerobic metabolism), glucose is converted to pyruvate, which enters the Krebs cycle; with anaerobic metabolism, lactate is formed. The oxidation of 1 mol of glucose requires 6 mol of O_2. Of the glucose taken up by the brain, 85 to 90 percent is oxidized; the remainder enters an amino acid pool and is utilized in the formation of proteins and other substances—notably neurotransmitters and particularly 3-aminobutyric acid (GABA).

When blood glucose falls, the CNS can utilize nonglucose substrates to a variable extent for its metabolic needs, especially keto acids and intermediates of glucose metabolism such as lactate, pyruvate, fructose, and other hexoses. In the neonatal brain, which has a higher glycogen reserve, keto acids provide a considerable proportion of cerebral energy requirements; this also happens after prolonged starvation. However, in the face of severe and sustained hypoglycemia, these nonglucose substrates are not adequate to preserve the structural integrity of neurons, and eventually adenosine triphosphate (ATP) is depleted as well. If convulsions occur, they usually do so during a period of mental confusion; the convulsions have been attributed to an altered integrity of neuronal membranes and to elevated NH_3 and depressed GABA and lactate levels (Wilkinson and Prockop).

The brain is the only organ besides the heart that suffers severe functional and structural impairment under conditions of severe hypoglycemia. Beyond what is described above, the pathophysiology of the cerebral disorder has not been fully elucidated. It is known that hypoglycemia reduces O_2 uptake and increases cerebral blood flow. As with anoxia and ischemia, there is experimental evidence that the excitatory amino acid glutamate is involved in the damaging process. The levels of several brain phospholipid fractions decrease when animals are given large doses of insulin. However, the suggestion that hypoglycemia results in a rapid depletion and inadequate production of high-energy phosphate compounds has not been corroborated; some other glucose-dependent biochemical process must be implicated.

**Etiology**

The most common causes of hypoglycemic encephalopathy are (1) accidental or deliberate overdose of insulin or an oral diabetic agent; (2) islet cell insulin-secreting tumor of the pancreas; (3) depletion of liver glycogen, which occasionally follows a prolonged alcoholic binge, starvation, or some form of acute liver disease such as acute nonicteric hepatomegaly of childhood (Reye syndrome); (4) glycogen storage disease of infancy; and (5) an idiopathic hypoglycemia in the neonatal period and, less often, of infancy. Moderate degrees of hypoglycemia (50 mg/dL) may be observed with chronic renal insufficiency (Fisher et al). In the past, hypoglycemic encephalopathy was a not infrequent complication of “insulin shock” therapy for schizophrenia. In functional hyperinsulinism, as occurs in anorexia nervosa and dietary faddism, the hypoglycemia is rarely of sufficient severity or duration to damage the CNS.

**Clinical Features**

The initial symptoms appear when the level of blood glucose has descended to about 30 mg/dL—nervousness, hunger, flushed faces, sweating, headache, palpitation, trembling, and anxiety. These gradually give way to confusion and drowsiness and occasionally to excitement, overactivity, and bizarre or combative behavior. Many of the early and mild symptoms relate to adrenal and sympathetic overactivity; therefore some of the manifestations may be muted in diabetic patients with neuropathy. In the next stage, forced sucking, grasping, motor restlessness, muscular spasms, and decerebrate rigidity occur, in that sequence. Myoclonic twitching and convulsions develop in some patients. Rarely there are focal cerebral deficits, the pathogenesis of which remains unexplained; according to Malouf and Brust, hemiplegia, corrected by intravenous glucose, was observed in 3 of 125 patients who presented with symptomatic hypoglycemia.

Blood glucose levels of approximately 10 mg/dL are associated with deep coma, dilatation of pupils, pale skin, shallow respiration, slow pulse, and hypotonia of limb musculature—the “medullary phase” of hypoglycemia. If glucose is administered before this level has been attained, the patient can be restored to normalcy, retracing the aforementioned steps in reverse order. However, once the medullary phase is reached, and particularly if it persists for a time before the hypoglycemia is corrected by intravenous glucose or spontaneously as a result of the gluconeogenic activities of the adrenal glands and liver, recovery is delayed for a period of days or weeks and may be incomplete as noted below.

The EEG is altered as the blood glucose falls, but the correlations are inexact. There is diffuse slowing in the theta or delta range. During recovery, sharp waves may appear and coincide in some cases with seizures. A large dose of insulin, which produces intense hypoglyce-
mia, even of relatively brief duration (30 to 60 min), is more dangerous than a series of less severe hypoglycemic episodes from smaller doses of insulin, possibly because the former impairs or exhausts essential enzymes—a condition that cannot then be overcome by large quantities of intravenous glucose.

The major clinical differences between hypoglycemic and hypoxic encephalopathy lie in the setting and the mode of evolution of the neurologic disorder. The effects of hypoglycemia usually unfold more slowly, over a period of 30 to 60 min, rather than in a few seconds or minutes. The recovery phase and sequelae of the two conditions are quite similar. A severe and prolonged episode of hypoglycemia may result in permanent impairment of intellectual function as well as other neurologic residua, like those that follow severe anoxia. We have also observed states of protracted coma as well as relatively pure Korsakoff amnesia. However, one should not be hasty in prognosis, for we have observed slow improvement to continue for 1 to 2 years.

Recurrent hypoglycemia, as with an islet cell tumor, may masquerade for some time as an episodic confusional psychosis or convulsive illness; diagnosis then awaits the demonstration of low blood glucose or hyperinsulinism in association with the neurologic symptoms. We saw a man in the emergency department whose main complaint was episodic inability to dial a touch-tone phone and a mild mental foginess; he was found to have an insulinoma.

According to Marks and Rose, who have written an authoritative monograph on the subject, lesser degrees and more chronic forms of low blood glucose may produce two other distinct but not mutually exclusive syndromes. One of these, categorized as subacute hypoglycemia, consists of drowsiness and lethargy, diminution in psychomotor activity, deterioration of social behavior, and confusion. Oral or intravenous glucose will immediately alleviate the symptoms. In the other syndrome, termed chronic hypoglycemia, there is a gradual deterioration of intellectual function, raising the question of dementia; in some reported instances, tremor, chorea, rigidity, cerebellar ataxia, and rarely signs of lower motor neuron involvement (hypoglycemic amyotrophy) are added. The last of these features has not been seen by the authors, who can only refer the reader to the report of Tom and Richardson.

These subacute and chronic forms of hypoglycemia have been observed in conjunction with islet cell hypertrophy and islet cell tumors of the pancreas, carcinoma of the stomach, fibrous mesothelioma, carcinoma of the cecum, and hepatoma. Supposedly an insulin-like substance is elaborated by these nonpancreatic tumors.

Functional or reactive hypoglycemia is the most ambiguous of all syndromes related to low blood glucose. This condition is usually idiopathic but may precede the onset of diabetes mellitus. The rise of insulin in response to a carbohydrate meal is delayed but then causes an excessive fall in blood glucose, to 30 to 40 mg/dL. The symptoms are malaise, fatigue, nervousness, headache, tremor, and so on, which may be difficult to distinguish from anxious depression. Not surprisingly, the term functional hypoglycemia has been much abused, being applied indiscriminately to a variety of complaints that would now be called chronic fatigue syndrome or simply anxiety neurosis. In fact, the syndrome of functional or reactive hypoglycemia is rare and its diagnosis requires the finding of an excessive reaction to insulin, a low blood glucose during the symptomatic period, and a salutary response to oral glucose. Treatment, which consists of a high-protein, low-carbohydrate diet, should be reserved for patients whose symptom complex correlates with pronounced hypoglycemia, as documented by a 5-h glucose tolerance test.

Pathologically, in all forms of hypoglycemic encephalopathy, the major damage is to the cerebral cortex. Cortical nerve cells degenerate and are replaced by microglial cells and astrocytes. The distribution of lesions is similar, though probably not identical to that in hypoxic encephalopathy. The cerebellar cortex is less vulnerable to hypoglycemia than to hypoxia. Auer has described the ultrastructural changes in neurons resulting from experimental hypoglycemia; with increasing duration of hypoglycemia and EEG silence, there are mitochondrial changes, first in dendrites and then in nerve cell soma, followed by nuclear membrane disruption leading to cell death.

Treatment of all forms of hypoglycemia obviously consists of correction of the hypoglycemia at the earliest possible moment. It is not known whether hypothermia or other measures will increase the safety period in hypoglycemia or alter the outcome. Seizures and twitching may not stop with anticonvulsants until the hypoglycemia is corrected.

Hyperglycemia

Two syndromes have been defined, mainly in diabetics: (1) hyperglycemia with ketoacidosis and (2) hyperosmolar nonketotic hyperglycemia.

In diabetic acidosis, the familiar picture is one of dehydration, fatigue, weakness, headache, abdominal pain, dryness of the mouth, stupor or coma, and Kussmaul type of breathing. Usually the condition has developed over a period of days in a patient known or proven to be diabetic. Often, the patient had failed to take a regular insulin dose. The blood glucose level is found to be more than 400 mg/dL, the pH of the blood less than 7.20, and the bicarbonate less than 10 meq/L. Ketone bodies and B-hydroxybutyric acid are elevated in the blood and urine, and there is a marked glycosuria. The prompt administration of insulin and repletion of intravascular volume correct the clinical and chemical abnormalities over a period of hours.

Of considerable interest is a small group of patients with diabetic ketoacidosis, such as those reported by Young and Bradley, in whom deepening coma and cerebral edema develop as the elevated blood level of glucose is corrected. Mild cerebral edema is commonly observed in children during treatment with fluids and insulin (Krane et al). This condition has been attributed by Procop to an accumulation of fructose and sorbitol in the brain. The latter substance, a polyol that is formed during hyperglycemia, crosses membranes slowly, but once it does so is said to cause a shift of water into the brain and an intracellular edema. However, according to Fishman, the increased polyols in the brain in hyperglycemia are not present in sufficient concentration to be important osmotically; they may induce other metabolic effects related to the encephalopathy. These are matters of conjecture, since the increase of polyols has never been found. The brain edema in this condition is probably due to reversal of the osmolality gradient from blood to brain, which occurs with rapid correction of hyperglycemia.

The pathophysiology of the cerebral disorder in diabetic ketoacidosis is not fully understood. No consistent cellular pathology of the brain has been identified in the cases we have examined. Factors such as ketosis, tissue acidosis, hypotension, hyperosmolality, and hypoxia have not been identified. Attempts at therapy by the administration of urea, mannitol, salt-poor albumin, and dexamethasone are usually unsuccessful, though recoveries are reported.

In hyperosmolar nonketotic hyperglycemia, the blood glucose
symptoms—astatereferredtoas
Chronic hepatic insufficiency with portocaval shunting of blood is portal-systemic encephalopathy (Hepatic Stupor and Coma, or hepatic or systemic shunt: Eck fistula) is attended by the same clinical picture, in which case the liver itself may be little or not at all affected (see further on). Also, there are a number of hereditary hyperammonemic syndromes, usually first apparent in infancy or childhood (see Chap. 37), that lead to episodic coma with or without seizures. In all these states, it is common for an excess of protein derived from the diet or from gastrointestinal hemorrhage to induce or worsen the encephalopathy. Additional predisposing factors are hypoxia, hypokalemia, metabolic alkalosis, excessive diuresis, use of sedative hypnotic drugs, and constipation. Reye syndrome, a special type of acute nonicteric hepatic encephalopathy of children, is also associated with very high levels of ammonia in the blood (see further on).

**Clinical Features** The clinical picture of acute, subacute, or chronic hepatic encephalopathy consists essentially of a derangement of consciousness, presenting first as mental confusion with decreased psychomotor activity, occasionally with hyperactivity, followed by progressive drowsiness, stupor, and coma. The confusional state, before coma supervenes, is combined with a characteristic intermittency of sustained muscle contraction; this phenomenon, which was originally described in patients with hepatic stupor by Adams and Foley and called *asterixis* (from the Greek *asterixis*, a “fixed position”), is now recognized as a sign of various metabolic encephalopathies but is most prominent in this disorder (page 86). It is conventionally demonstrated by having the patient hold his arms outstretched with the wrists extended, but the same tremor can be elicited by any sustained posture, including that of the protruded tongue. A variable, fluctuating rigidity of the trunk and limbs, grimacing, suck and grasp reflexes, exaggeration or asymmetry of tendon reflexes, Babinski signs, and focal or generalized seizures round out the clinical picture in a few patients.

The EEG is a sensitive and reliable indicator of impending coma, becoming abnormal during the earliest phases of the deranged mental state. Watson and Adams noted an EEG abnormality consisting of paroxysms of bilaterally synchronous slow or triphasic waves in the delta range, which at first predominate frontally and are interspersed with alpha activity and later, as the coma deepens, displace all normal activity (Fig. 2-3H, page 27). A few patients show only random high-voltage asynchronous slow waves.

This syndrome of hepatic encephalopathy is remarkably diverse in its course and evolution. It usually appears over a period of days to weeks and may terminate fatally; or, with appropriate treatment, the symptoms may regress completely or partially and then fluctuate in severity for several weeks or months. Persistent hepatic coma of the latter type proves fatal in about half of patients (Levy et al). In many patients, the syndrome is relatively mild and does not evolve beyond the stage of mental dullness and confusion, with asterixis and EEG changes. In yet others, a subtle disorder of mood, personality, and intellect may be protracted over a period of many months or even years; this chronic but nevertheless reversible mental disturbance need not be associated with overt clinical signs of liver failure (mainly jaundice and ascites) or other neurologic signs. Characteristically in these patients, an extensive portal-systemic collateral circulation can be demonstrated (hence the term *portal-systemic encephalopathy*) and an association established between the mental disturbance and an intolerance to dietary protein as well as raised blood ammonia levels (Summerskill et al).

The diversion of blood from the portal system into the vena cava after ligation of the portal veins was first performed in dogs by Eck in 1877. Probably the first and certainly most striking example in man was the case of pure Eck fistula reported by McDermott and Adams, in which a portacaval shunt was created during the removal of a pancreatic tumor. The liver was normal. Episodic coma occurred thereafter whenever dietary protein increased. Consciousness was restored on a protein-free diet, and coma could be induced again by ammonium chloride. Postmortem examination 2 years later confirmed the normal liver and showed cerebral changes of hepatic encephalopathy, as described below.

Finally, there is a group of patients (most of whom have experienced repeated attacks of hepatic coma) in whom an irreversible mild dementia and a disorder of posture and movement (grimming, tremor, dysarthria, ataxia of gait, choreoathetosis) gradually appear. This condition of *chronic acquired hepatocerebral degeneration* must be distinguished from other dementing and extrapyramidal syndromes (see further on). A few cases of isolated spastic-ataxic paraplegia (so-called *hepatic myelopathy*) of unclear nature have also been described (page 1078).

The concentrations of blood NH₃, particularly if measured repeatedly in arterial blood samples, usually are well in excess of 200 mg/dL, and the severity of the neurologic and EEG disorders roughly parallels to the ammonia levels. With treatment, a fall in the NH₃ levels precedes clinical improvement. In the past, a provocative test of an oral dose of 6.0 g of NH₄Cl was used in uncertain cases to produce mild symptoms of hepatic encephalopathy.

**Neuropathologic Changes** The striking finding by Adams and Foley in patients who die in a state of hepatic coma is a diffuse increase in the number and size of the protoplasmic astrocytes in the deep layers of the cerebral cortex, lenticular nuclei, thalamus, substantia nigra, cerebellar cortex, and red, dentate, and pontine
nuclei, with little or no visible alteration in the nerve cells or other parenchymal elements. With periodic acid–Schiff (PAS) staining, the astrocytes are seen to contain characteristic glycogen inclusions. These abnormal glial cells are generally referred to as Alzheimer type II astrocytes, having been described originally in 1912 by von Hansemann and Alzheimer in a patient with Westphal–Strümpell pseudosclerosis (familial hepatoenteric degeneration, or Wilson disease). These astrocytes have been studied by electron microscopy in rats with surgically created portacaval shunts (Cavanagh; Norenberg); the cells show a number of striking abnormalities—swelling of their terminal processes, cytoplasmic vacuolation (distended sacs of rough endoplasmic reticulum), formation of folds in the basement membrane around capillaries, and an increase in both the number of mitochondria and enzymes that catalyze ammonia. Also, some degeneration in myelinated nerve fibers in the neuropil and an increase in the cytoplasm of oligodendrocytes are seen. In chronic cases, we have found neuronal loss in the deep layers of the cerebrum and cerebellar cortex and in the lenticular nuclei as well as a vacuolization of tissue (possibly astrocyte vacuolation) resembling the lesions of Wilson disease.

The ubiquitous astrocytic alterations occur to some degree in all patients who die of progressive liver failure, and the degree of this glial abnormality corresponds generally to the intensity and duration of the neurologic disorder. Possibly, the astrocytic changes affect the synaptic activities of the neurons. The clinical and EEG features of hepatic encephalopathy as well as the astrocytic hyperplasia are more or less specific features of this metabolic disorder. Nevertheless, taken together in a setting of liver failure, they constitute a distinctive clinicopathologic entity.

Pathogenesis of Hepatic Encephalopathy The most plausible hypothesis relates hepatic coma to an abnormality of nitrogen metabolism, wherein ammonia, which is formed in the bowel by the action of urease-containing organisms on dietary protein, is carried to the liver in the portal circulation but fails to be converted into urea because of either hepatocellular disease, portal-systemic shunting of blood, or both. As a result, excess amounts of NH₃ reach the systemic circulation, where they interfere with cerebral metabolism in a way that is not yet fully understood. Certainly the ammonia theory best explains the basic neuropathologic change. Norenberg has proposed that the hypertrophy of the astrocytic cytoplasm and proliferation of the mitochondria and endoplasmic reticulum, as well as the increase in the astroglial glutamic dehydrogenase activity, reflect the heightened metabolic activity associated with ammonia detoxification. Removal of brain ammonia depends on the formation of glutamine, a reaction that is catalyzed by the ATP-dependent enzyme glutamine synthetase, which is localized in the astrocytes. It has been shown in experimental animals that hyperammonemia leads to a depletion of ATP in midbrain reticular nuclei. Whether this is the primary cause of coma has not been resolved.

Numerous alternative theories have been suggested, but most can be discounted or are unproved. One is that CNS function in cirrhotic patients is impaired by phenols or short-chain fatty acids derived from the diet or from bacterial metabolism of carbohydrate. Another theory holds that biogenic amines (e.g., octopamine), which arise in the gut and bypass the liver, act as false neurotransmitters, displacing norepinephrine and dopamine (Fischer and Baldessarini). Zieve has presented evidence that mercaptans (methanethiol, methionine), which are also generated in the gastrointestinal tract and removed by the liver, act in conjunction with NH₃ to produce hepatic encephalopathy. This theory and others has been the subject of reviews by Butterworth and coworkers, by Zieve, by Rothstein and Herlong, and by Jones and Basile, to which the reader is referred for detailed information.

Also in recent years, manganese has emerged as a potential neurotoxin in the pathogenesis of hepatic encephalopathy (Kreiger et al; Pomier-Layrargues et al). In patients with chronic liver disease and with spontaneous or surgically induced portal-systemic shunts, manganese accumulates in the serum and in the brain, more specifically in the pallidum. This accumulation is readily discernible as a pallidal signal hyperintensity on T1-weighted MRI. Following liver transplantation, there is normalization of the MRI changes and of the associated extrapyramidal symptoms. The effects of manganese chelation on such patients have not been studied, and the mechanisms of accumulated manganese in the pathogenesis of hepatic encephalopathy are not known. None in our view is as persuasive as the case for ammonia. For some time, it has been known that hepatic encephalopathy is associated with increased activity of the inhibitory transmitter GABA in the cerebral cortex. It has also been observed that increased GABA-ergic neurotransmission may result from substances that inhibit the binding of endogenous benzodiazepine-like compounds to their receptors (Basile et al). Furthermore, these antagonists are found to have some clinical effect—transient arousal in patients with hepatic encephalopathy. The actions of benzodiazepines are mediated by these receptors; hence the designation GABA-benzodiazepine theory. The practicality of using benzodiazepine receptor antagonists, which are short-acting and reversible (e.g., flumazenil), in the treatment of hepatic encephalopathy remains to be determined (see Mullen), but they offer an interesting diagnostic test.

Until recently, the ammonia and the GABA-ergic-benzodiazepine hypotheses of the pathogenesis of hepatic encephalopathy had appeared to be unrelated and even mutually exclusive. However, there is evidence, reviewed by Jones and Basile, that ammonia, even in the modestly elevated concentrations that occur in liver failure, enhances GABA-ergic neurotransmission—a concept that may unify the two mechanisms.

Treatment Despite the incompleteness of our understanding of the role of disordered ammonia metabolism in the genesis of hepatic coma, an awareness of this relationship has provided the few effective means of treating this disorder: restriction of dietary protein; reduction of bowel flora by oral administration of neomycin or kanamycin, which suppress the urease-producing organisms in the bowel; and the use of enemas. The mainstay of treatment has been oral lactulose, an inert sugar that acidifies the colonic contents and greatly reduces bacterial activity. The sustained use of oral neomycin carries a risk of renal damage and ototoxicity and has therefore been relegated to second-line therapy. The salutary effects of these therapeutic measures, the common attribute of which is the lowering of the blood NH₃, further supports the theory of ammonia intoxication. Ultimately, in cases of intractable liver failure, transplantation becomes a treatment of last resort.

Other treatments, the values of which remain to be established, include the use of bromocriptine, the diazepine antagonist flumazenil, and keto-analogues of essential amino acids. Theoretically, the keto-analogues should provide a nitrogen-free source of essential amino acids (Maddrey et al), and bromocriptine, a dopamine agonist, should enhance dopaminergic transmission (Morgan et al). Administration of branched-chain amino acids may result in considerable improvement in mental status, but their effects have
been variable and associated with an increased mortality (Naylor et al). The transient beneficial effects of the benzodiazepine antagonist flumazenil have already been mentioned.

**Fulminant Hepatic Failure and Cerebral Edema** In *acute hepatitis*, confusional, delirious, and comatose states also occur, but their mechanisms are still unknown. Blood NH₃ may be elevated, but usually not to a degree that would be expected to affect the brain. Severe acute hepatic failure may cause hypoglycemia, which contributes to the encephalopathy and often presages a fatal outcome, but the levels of glucose typically detected do not provide an explanation for the encephalopathy.

Cerebral edema is a prominent finding in cases of fulminant hepatic failure from any cause and is the main cause of death in patients awaiting liver transplantation. The cerebral edema that occurs in these circumstances appears to be related to the rapidity of rise of blood ammonia, but it probably depends as well on additional metabolic derangements that complicate acute liver failure. The combination of rapidly evolving hepatic failure and massive cerebral edema is similar to that observed in the Rey syndrome, described below.

CT scanning is an effective means of detecting cerebral edema in patients with fulminant hepatic failure, and according to Wijdicks and colleagues, the degree of cerebral swelling is roughly proportional to the severity of encephalopathy. Since patients with fulminant hepatic failure can survive liver transplantation with few or no neurologic deficits, it is important to recognize cerebral edema early, before the stages of stupor and coma and greatly increased intracranial pressure have been established. Short of transplantation, death in these cases may sometimes be prevented by monitoring the intracranial pressure (as outlined by Lidofsky et al) and by the use of osmotic diuretics and hyperventilation, as detailed in Chaps. 31 and 35. Some survivors are nonetheless left with cerebral damage from raised intracranial pressure.

An additional issue that arises in assessing cerebral dysfunction in patients with liver disease is the possibility of adverse effects of medications. Individuals with hepatitis C who are treated with interferon alpha may develop a spectrum of problems ranging from subtle cognitive impairment to a subacutely worsening headache, vomiting, altered consciousness, and focal neurologic findings. The milder syndromes are associated with no or few MRI-visible lesions, but the severe ones are usually accompanied by signal changes in the white matter of the occipital lobes and elsewhere (posterior leukoencephalopathy, page 1040).

**Reye Syndrome (Reye-Johnson Syndrome)** This is a special type of nonicteric hepatic encephalopathy occurring in children and adolescents and characterized by acute brain swelling in association with fatty infiltration of the viscera, particularly the liver. Although individual cases of this disorder had been described for many years, its recognition as a clinical-pathologic entity dates from 1963, when a large series was reported from Australia by Reye and colleagues and from the United States by Johnson and coworkers. The disorder tends to occur in outbreaks (286 cases were reported to the Centers for Disease Control during a 4-month period in 1974). Mainly, these outbreaks were observed in association with influenza B virus and varicella infections, but a variety of other viral infections were implicated (influenza A, echovirus, reovirus, rubella, rubeola, herpes simplex, Epstein-Barr virus). Later it became apparent that the toxic or adjuvant effects of aspirin given during these infections played an important role in producing the disease. Only occasional instances of Rey syndrome are observed now that the association with aspirin administration has become widely known and its use in children with viral infections has been interdicted.

Most patients are children, boys and girls being equally affected, but rare instances are known in infants (Huttenlocher and Trauner) and young adults. In most cases the encephalopathy is preceded for several days to a week by fever, symptoms of upper respiratory infection, and protracted vomiting. These are followed by the rapid evolution of stupor and coma, associated in many cases with focal and generalized seizures, signs of sympathetic overactivity (tachypnea, tachycardia, mydriasis), decorticate and decerebrate rigidity, and loss of pupillary, corneal, and vestibulo-ocular reflexes. One or two such cases were included in the series of acute “toxic encephalopathy” reported by Lyon and colleagues (page 603). In infants, respiratory distress, tachypnea, and apnea are the most prominent features.

The liver may be greatly enlarged, often extending to the pelvis and providing an important diagnostic clue as to the cause of the cerebral changes. Initially there is a metabolic acidosis, followed by a respiratory alkalosis (rising arterial pH and falling PCO₂). The CSF is usually under increased pressure and is acellular; glucose values may be low, reflecting the hypoglycemia. The serum glutamic-oxaloacetic transaminase (SGOT), coagulation times, and blood ammonia are increased, sometimes to an extreme degree. The EEG is characterized by diffuse arrhythmic delta activity, progressing to electrocerebral silence in patients who fail to survive. CT and MRI show the cerebral swelling but are difficult to interpret in these young individuals, who lack any adult brain atrophy.

The major pathologic findings are cerebral edema, often with cerebellar herniation, and infiltration of hepatocytes with fine droplets of fat (mainly triglycerides); the renal tubules, myocardium, skeletal muscles, pancreas, and spleen are infiltrated to a lesser extent. There are no inflammatory lesions in the brain, liver, or other organs. There is not full agreement as to the pathogenesis of this disorder.

**Prognosis and Treatment** In a series of children with blood ammonia levels greater than 500 mg/dL who were treated during the years 1967 to 1974, Shaywitz and colleagues reported a mortality of 60 percent. Once the child became comatose, death was almost inevitable. In more recent years, early diagnosis and initiation of treatment before the onset of coma have reduced the fatality rate to 5 to 10 percent. Treatment consists of the following measures: temperature control with a cooling blanket; nasotracheal intubation and controlled ventilation to maintain PCO₂ below 32 mmHg; intravenous glucose covered by insulin to maintain blood glucose at 150 to 200 mg/dL; administration of lactulose and neomycin enemas; control of intracranial pressure by means of continual monitoring and the use of hypotonic solutions (see Chap. 30); and the maintenance of fluid and electrolyte balance (Trauner). Upon recovery, cerebral function returns to normal unless there had been deep and prolonged coma or protracted elevation of intracranial pressure.

**Uremic Encephalopathy and Twitch-Convulsive Syndrome**

Episodic confusion and stupor and other neurologic symptoms may accompany any form of severe renal disease—acute or chronic. The cerebral symptoms attributable to uremia (first described by
Addison in 1832) are best discerned in normotensive individuals in whom renal failure develops rapidly. Apathy, fatigue, inattention, and irritability are usually the initial symptoms; later, there is confusion, disturbance of sensory perception, hallucinations, dysarthria, tremor, and asterixis. Infrequently this takes the form of a toxic psychosis, with hallucinations, delusions, insomnia, or catatonia (Marshall). Characteristically these symptoms fluctuate from day to day or even from hour to hour. In some patients, especially those who become anuric, symptoms may come on rather abruptly and progress rapidly to a state of stupor and coma. In others, in whom uremia develops more gradually, mild visual hallucinations and a disorder of attention may persist for several weeks in relatively pure form. The EEG becomes diffusely and irregularly slow and may remain so for several weeks after the institution of dialysis. The CSF pressure is normal and the protein is not elevated unless there is a uremic or diabetic neuropathy. In several reports, meningeismus and a low-grade mononuclear pleocytosis is mentioned, but we have not found this.

In acute renal failure, clouding of the sensorium is practically always associated with a variety of motor phenomena, which usually occur early in the course of the encephalopathy, sometimes when the patient is still mentally clear. The patient begins to twitch and jerk and may convulse. The myoclonic twitches involve parts of muscles, whole muscles, or limbs and are lightning-quick, arrhythmic, and asynchronous on the two sides of the body; they are incessant during both wakefulness and sleep. At times the movements resemble those of chorea or an arrhythmic tremor; asterixis is also readily evoked. The motor phenomena are often difficult to classify. The authors have preferred to describe the condition as a uremic twitch-convulsive syndrome.

Because of the similarity of this syndrome to tetany, measurement should be made of serum calcium and magnesium—and, of course, hypocalcemia and hypomagnesemia do occur in uremia. But often the values for these ions are normal or near normal, and the administration of calcium and magnesium salts has little effect. The resemblance of uremic encephalopathy to hepatic and other metabolic encephalopathies has been stressed by Raskin and Fishman, yet we are more impressed with differences than with similarities. We have observed the twitch-convulsive syndrome in association with a variety of diseases such as widespread neoplasia, delirium tremens, diabetes with necrotizing pyelonephritis, and lupus erythematous, in which the blood urea nitrogen was only modestly elevated; but always the factor of renal failure was ultimately discovered.

As the uremia worsens, the patient lapses into a quiet coma. Unless the accompanying metabolic acidosis is corrected, Kussmaul breathing appears and gives way to Cheyne-Stokes breathing and death.

It is important to keep in mind that encephalopathy and coma in the patient with renal failure may be due to disorders other than uremia itself. The altered excretion of drugs leads to their accumulation, sometimes evoking excessive sedation even though serum concentrations are normal. Subdural and intracerebral hemorrhages may complicate uremia (and dialysis) because of clotting defects and hypertension, and chronically azotemic patients are prone to infections, including meningitis.

Since chronic uremia is so frequently associated with hypertension, a major problem also arises in distinguishing the cerebral effects of uremia from those of severe and accelerated hypertension. Volhard was the first to make this distinction; he introduced the term pseudouremia to designate the cerebral effects of malignant hypertension and to separate them from true uremia. The term hypertensive encephalopathy, by which pseudouremia is now known, was first used by Oppenheimer and Fishberg. However, the myoclonic-twitch syndrome is not a component of hypertensive encephalopathy. The clinical picture of the latter disorder and its pathophysiology are discussed on page 728.

Pathogenesis Opinions vary widely as to the biochemical basis of uremic encephalopathy and the twitch-convulsive syndrome. Restoration of renal function completely corrects the neurologic syndrome, attesting to a functional disorder of subcellular type. Whether caused by the retention of organic acids, elevation of phosphate in the CSF (claimed by Harrison et al), or the action of urea or other toxins has never been settled. The data supporting the causative role of urea are ambiguous, just as they are for other putative endogenous agents (see Bolton and Young and the review by Burn and Bates). However, it can be stated that urea itself is not the sole inductive agent, since its infusion does not produce the syndrome in man or animals.

It would appear that every level of the CNS is affected, from spinal cord to cerebrum. The authors have been unable to detect cellular changes in the brain or spinal cord other than a mild hydropenia of protoplasmic astrocytes in some cases, but never of the degree observed in hepatic encephalopathy. Cerebral edema is notably absent. In fact, CT scans and MRI regularly show an element of cerebral shrinkage, probably on the basis of hyperosmolality. A peripheral neuropathy is also a common complication of uremia and is considered in Chap. 46.

Treatment In the treatment of uremic encephalopathy, the nature of the renal disease assumes paramount importance; if it is irreversible and progressive, the prognosis is poor without dialysis or renal transplantation. Improvement of encephalopathic symptoms may not be evident for a day or two after institution of dialysis. Convulsions, which occur in about one-third of cases, often preterminally, may respond to relatively low plasma concentrations of anticonvulsants, the reason being that serum albumin is depressed in uremia, increasing the unbound, therapeutically active portion of a drug. If there are severe associated metabolic disturbances, such as hyponatremia, the seizures may be difficult to control. One must be cautious in prescribing any of a large number of drugs in the face of renal failure, for inordinately high, toxic blood levels may result. Examples are aminoglycoside antibiotics (vestibular damage); furosemide (cochlear damage); and nitrofurantoin, isoniazid, and hydralazine (peripheral nerve damage).

Dialysis "Disequilibrium Syndrome" This term refers to a group of symptoms that may occur during and following hemodialysis or peritoneal dialysis in association with some degree of cerebral edema. The symptoms include headaches, nausea, muscle cramps, nervous irritability, agitation, drowsiness, and convulsions. The headache, which may be bilateral and throbbing and resemble common migraine, develops in approximately 70 percent of patients, while the other symptoms are observed in 5 to 10 percent, usually in those undergoing rapid dialysis or in the early stages of a dialysis program. The symptoms tend to occur in the third or fourth hour of dialysis and last for several hours. Sometimes they appear 8 to 48 h after the completion of dialysis. Originally these symptoms were attributed to the rapid lowering of serum urea, leaving the brain with a higher concentration of urea than the serum and resulting in a shift of water into the brain to equalize the os-
motic gradient (reverse urea syndrome). Now it is believed that the shift of water into the brain is akin to water intoxication and is due to the inappropriate secretion of antidiuretic hormone.

The symptoms of subdural hematoma, which in some series had in the past occurred in 3 to 4 percent of patients undergoing dialysis, now being less frequent, may be mistakenly attributed to the disequilibrium syndrome.

**Dialysis Encephalopathy (Dialysis Dementia)** This is a sub-acute ly progressive syndrome that in the past complicated chronic hemodialysis. Characteristically the condition begins with a hesitant, stuttering dysarthria, dysphasia, and sometimes apraxia of speech, to which are added facial and then generalized myoclonus, focal and generalized seizures, personality and behavioral changes, and intellectual decline. The EEG is invariably abnormal, taking the form of paroxysmal and sometimes periodic sharp-wave or spike-and-wave activity (up to 500 mV and lasting 1 to 20 s), intermixed with abundant theta and delta activity. The CSF is normal except occasionally for increased protein.

At first the myoclonus and speech disorders are intermittent, occurring during or immediately after dialysis and lasting for only a few hours, but gradually they become more persistent and eventually permanent. Once established, the syndrome is usually steadily progressive over a 1- to 15-month period (average survival of 6 months in the 42 cases analyzed by Lederman and Henry).

The neuropathologic changes are said to be subtle and consist of a mild degree of microcavitation of the superficial layers of the cerebral cortex. Although the changes are diffuse, they have been found in one study to be more severe in the left (dominant) hemisphere than in the right and more severe in the left frontotemporal operculum than in the surrounding cortex (Winkelman and Ricanati). The disproportionate affection of the left frontotemporal opercular cortex putatively explains the distinctive disorder of speech and language. In the one case we have studied carefully, we could not be certain of any microscopic changes.

The most plausible view of the pathogenesis of dialysis encephalopathy is that it represented a form of aluminum intoxication (Alfrey et al), the aluminum being derived from the dialysate or from orally administered aluminum gels. In recent years, this disorder has disappeared, the result, in all likelihood, of the universal practice of purifying the water used in dialysis and thereby removing aluminum from the dialysate. This subject has been reviewed by Parkinson and coworkers.

**Complications of Renal Transplantation** The risk in immunosuppressed persons of developing a primary lymphoma of the brain or progressive multifocal leukoencephalopathy is well known and has been mentioned in previous chapters (page 651). An entirely different encephalopathy that is marked by widespread visual symptoms and edema of the cerebral white matter, evident on the MRI, but mainly occipital occurs after the administration of cyclosporine and other immunosuppressant drugs. The pattern “reversible posterior leukoencephalopathy” on MRI is not specific, being seen also in patients with hypertensive encephalopathy, eclampsia, intrathecal methotrexate, and other conditions (see Table 43-1, page 1040). Systemic fungal infections had in the past been found at autopsy in about 45 percent of patients who had had renal transplants and long periods of immunosuppressive treatment; in about one-third of these patients, the CNS was involved. Cryptococcus, Listeria, Aspergillus, Candida, Nocardia, and Histoplasma are the usual organisms. Recent experience suggests a lower rate of infection. Other CNS infections that have complicated transplantation are toxoplasmosis and cytomegalic inclusion disease.

In some nutritionally depleted uremic patients who are subjected to treatment that involves major shifts of plasma water and electrolytes, diseases unrelated to uremia may develop. In our necropsy material, we have also found examples of Wernicke-Korsakoff disease and central pontine myelinolysis. A bleeding diathesis may result in subdural or cerebral hemorrhage, as already mentioned.

**Encephalopathy Associated with Sepsis and Burns**

Bolton and Young have drawn attention to the frequent occurrence, in severely septic patients, of a drowsy or confusional state that is reversible and not explained by hepatic, pulmonary, or renal failure, electrolyte imbalance, hypotension, drug intoxication, or a primary lesion of the brain. They called the condition “septic encephalopathy.” According to their surveys, 70 percent of patients become disoriented and confused within hours of the onset of severe systemic infection; in a few cases, this state may progress to stupor and coma. Notably there are no signs of asterixis, myoclonus, or focal cerebral disorder, but paratonia is common, as is the later development of a polyneuropathy.

The encephalopathic state that occurs with severe systemic infection may also develop independently of sepsis, as a component of a syndrome of multiple organ failure and, according to some authors, a complication of widespread cutaneous burns (Aikawa et al). Others of our colleagues have questioned the validity of this last category and have instead found explanatory electrolyte disorders (particularly hyponatremia, see page 974), sepsis, or multiple brain abscesses (Winkelman, personal communication).

It has been useful in clinical work to distinguish these encephalopathies of infection and multiorgan failure from those due to isolated hepatic or renal disease. The lack of a biochemical marker and the confounding effects of hypotension during sepsis (septic shock) leave doubt as to pathogenesis. Altered phenylalanine metabolism and circulating cytokines have been proposed as causes, without firm evidence. Of interest in two of our fatal cases was the presence of brain purpura, but this has otherwise been an infrequent finding. Here, the white matter of the cerebrum and cerebellum was speckled with myriads of pericapillary hemorrhages and zones of pericapillary necrosis. This pathologic reaction is nonspecific, having also been seen in some of our cases of viral pneumonia, heart failure with morphine overdose, and arsenic intoxication.

**Disorders of Sodium, Potassium, and Water Balance**

Drowsiness, confusion, stupor, and coma, in conjunction with seizures and sometimes with other neurologic deficits, may have as their basis a more or less pure abnormality of electrolyte or water balance. Only brief reference is made to some of these—such as hypocalcemia, hypercalcemia, hypophosphatemia, and hypomagnesemia—since they are considered in other parts of the text.

**Hyponatremia** Among the many causes of hyponatremia, the syndrome of inappropriate antidiuretic hormone secretion (SIADH) is of special importance, because it may complicate neurologic diseases of many types—head trauma, bacterial meningitis
and encephalitis, cerebral infarction, subarachnoid hemorrhage, neoplasm, and Guillain-Barré syndrome. The diagnosis of SIADH should be suspected in any critically ill neurologic or neurosurgical patient who excretes urine that is hypertonic relative to the plasma. As the hyponatremia develops, there is a decrease in alertness, which progresses through stages of confusion to coma, often with convulsions. As with many other metabolic derangements, the severity of the clinical effect is related to the rapidity of decline in serum Na. Lack of recognition of this state may allow the serum Na to fall to dangerously low levels, 100 meq/L or lower. One’s first impulse is to administer NaCl intravenously, but this must be done cautiously, because in most of these patients the intravascular volume is already expanded and there is a risk of congestive heart failure. Most cases respond to the restriction of fluid intake—to 500 mL per 24 h if the serum Na is less than 120 meq/L and to 1000 mL per 24 h if less than 130 meq/L. Even when the Na reaches 130 meq/L, the fluid intake should not exceed 1500 mL per 24 h.

In extreme cases of hyponatremia with stupor or seizures, infusion of NaCl is necessary. The amount of NaCl to be infused can be calculated from the current and the target levels of serum Na by assuming that the infused sodium load is distributed throughout the total body water content (0.6 weight in kilograms):

\[ [(\text{Target Na} - \text{starting Na}) \times 0.6] \times \text{weight (kg)} = \text{infused Na load (meq)} \]

The desired volume of normal saline can then be determined by keeping in mind that its sodium concentration is 154 meq/L and that of 3 percent (hypertonic) saline solution is 462 meq/L. If hypertonic saline is administered, it is usually necessary to simultaneously reduce intravascular volume with furosemide, beginning with a dose of 0.5 mg/kg intravenously, and to increase the dosage until a diuresis is obtained. Guidelines to prevent an overly rapid correction of Na are elaborated further on in relation to central pontine myelinolysis (no more than 10 mmol/L in the first 24 h). Although the syndrome of SIADH is usually self-limiting, it may continue for weeks or months, depending on the type of associated brain disease.

It must be emphasized that not all patients with intracranial disorders who manifest hyponatremia and natriuresis have SIADH. In fact, in many such patients, renal loss of salt is the cause of hyponatremia and, in contrast to SIADH, results in decreased blood volume. This process has been termed “cerebral salt wasting” (Nelson et al). Sodium loss in these circumstances is attributable to the production by the heart or brain of a potent polypeptide, atrial natriuretic factor. As discussed in Chap. 34, under “Subarachnoid Hemorrhage,” the distinction between SIADH and cerebral salt wasting is of more than theoretical importance, insofar as fluid restriction to correct hyponatremia may be dangerous in patients with salt wasting, particularly in those with vasospassm after ruptured intracranial aneurysms.

Arieff has emphasized the hazards of postoperative hyponatremia in a series of 15 patients, all of them women, in whom severe hyponatremia followed elective surgery. About 48 h after these patients had recovered from anesthesia, their serum Na fell to an average level of 108 meq/L; the urinary sodium to 68 mmol/L, and the urinary osmolality was 501 mosmol/kg, at which point generalized seizures occurred, followed by respiratory arrest. Of the 15 women, 5 died, but there were no diagnostic pathologic findings and no lesions of central pontine myelinolysis (see below). Seven patients whose serum Na was corrected slowly improved over a period of several days but then developed progressive drowsiness and increasing nausea, headache, and obtundation, followed by a recurrence of seizures and coma. These patients survived in a persistent vegetative state. We find the syndrome difficult to interpret and have not encountered cases of this sort. The initial hyponatremia may have been the result of SIADH.

An important consideration in the management of severe hyponatremia and hyperosmolality, as mentioned earlier, is the rapidity with which these abnormalities are corrected and the danger of provoking central pontine myelinolysis and related brainstem, cerebellar, and cerebral lesions (extrapontine myelinolysis). These issues are considered below, in the section on central pontine myelinolysis.

### Hyponatremia

**Severe hyponatremia** (Na >155 meq/L) and dehydration are observed in diabetes insipidus, the neurologic causes of which include head trauma with damage to the pituitary stalk (Chap. 27), and in nonketotic diabetic coma, protracted diarrhea in infants, and the deprivation of fluid intake in the stuporous patient. The last condition is usually associated with a brain lesion that impairs consciousness. Exceptionally, in patients with chronic hydrocephalus, the hypothalamic thirst center is rendered inactive, and severe hyponatremia, stupor, and coma may follow a failure to drink. In hyponatremia from any cause, the brain volume is manifestly reduced in CT scans. Retraction of the cerebral cortex from the dura has been known to rupture a bridging vein and cause a subdural hematoma.

As is true for hyponatremia, the degree of CNS disturbance in hypernatremia is generally related to the rate at which the serum Na rises. Slowly rising values, to levels as high as 170 meq/L, may be surprisingly well tolerated. Rapid elevations of sodium shrink the brain, especially in infants. Extremely high levels cause impairment of consciousness with asterixis, myoclonus, seizures, and choreiform movements. In addition, muscular weakness, rhabdomyolysis, and myoglobinuria have been reported.

It should be noted that hyponatremia is usually accompanied by hypo-osmolality of the serum and hypernatremia by hyperosmolality. However, there is no strict correlation between serum osmolarity and neurologic dysfunction. Instead, the rapidity of change, as already emphasized, plays a major role. In hyponatremia plus hypo-osmolality, Fishman finds an increase in intracellular water and a diminution in intracellular K; but in our view it is the dehydration that is more critical and coincides with the neuronal derangement. In hypernatremia plus hyperosmolality, the neurons do not lose water as much as do other cells, a compensatory reaction that Fishman had attributed to the presence of “idiogenic osmoles”—possibly glucose, glucose metabolites, and amino acids. The impairment of neuronal function in this state is not understood. Theoretically one would expect neuronal shrinkage and possibly alteration of the synaptic surface of the cell.

### Hypo- and Hyperkalemia

The main clinical effect of hypokalemia (K, 2.0 meq/L or less) is generalized muscular weakness (see Chap. 48). A mild confusional state may also be added but is very infrequent. The condition is readily corrected by adding K to intravenous fluid and infusing it at no more than 4 to 6 meq/h. Hyperkalemia (above 7 meq/L) also may manifest itself by generalized muscle weakness, although the main effects are changes in the electrocardiogram (ECG), possibly leading to cardiac arrest.
Other Metabolic Encephalopathies

Limitation of space permits only brief reference to other metabolic disturbances that may present as episodic confusion, stupor, or coma. The most important members of this group are summarized below.

**Hypercalcemia**

This is defined as an elevation of the serum calcium concentration above 10.5 mg/dL. If the serum protein content is normal, Ca levels greater than 12 mg/dL are required to produce neurologic symptoms. However, with low serum albumin levels, an increased proportion of the serum Ca is in the unbound or ionized form (upon which the clinical effects depend), and symptoms may occur with serum Ca levels as low as 10 mg/dL.

In young persons, the most common cause of hypercalcemia is hyperparathyroidism (either primary or secondary); in older persons, osteolytic bone tumors, particularly metastatic carcinoma and multiple myeloma, are often causative. Less common causes are vitamin D intoxication, prolonged immobilization, hyperthyroidism, sarcoidosis, and decreased calcium excretion (renal failure).

Anorexia, nausea and vomiting, fatigue, and headache are usually the initial symptoms, followed by confusion (rarely a delirium) and drowsiness, progressing to stupor or coma in untreated patients.

A history of recent constipation is common. Diffuse myoclonus and rigidity occur occasionally, as do elevations of spinal fluid protein (up to 175 mg/100 mL). Convulsions are uncommon.

**Hypocalcemia**

The usual manifestations are paresthesias, tetany, and seizures. With severe and persistent hypocalcemia, altered mental status in the form of depression, confusion, dementia, or personality change can occur. Anxiety to the point of panic attack is also known. Even coma may result, in which case there may be papilledema due to increased intracranial pressure. Aside from the raised pressure, the CSF shows no consistent abnormality. This increase in intracranial pressure may be manifest by headache and papilledema without altered mentation or with visual obscurations.

Hypoparathyroidism is discussed again further on, in the section on extrapyramidal syndromes.

**Other Electrolyte and Acid-Base Disorders**

Severe metabolic acidoses from any cause produces a syndrome of drowsiness, stupor, and coma, with dry skin and Kussmaul breathing. The CNS depression does not correlate with the concentration of ketones. Possibly, there are associated effects on neurotransmitters. It is often not possible to separate the effects of acidosis from those due to an underlying condition or toxic ingestion.

In infants and children, acidosis may occur in the course of hyperammonemia, isovaleric acidemia, maple syrup urine disease, lactic and glutaric acidemia, hyperglycinemia, and other disorders, which are described in detail in Chap. 37. High-voltage slow activity predominates in the EEG, and correction of the acidosis or elevated ammonia level restores CNS function to normal provided that coma was not prolonged or complicated by hypoxia or hypotension. In uncomplicated acidotic coma, we have observed no recognizable neuropathologic change by light microscopy.

Encephalopathy due to Addison disease (adrenal insufficiency) may be attended by episodic confusion, stupor, or coma without special identifying features; it is usually precipitated in the addisonian patient by infection or surgical stress. Hemorrhagic destruction of the adrenals in meningococcal meningitis (Waterhouse-Friderichsen syndrome) is another cause. Hypotension and diminished cerebral circulation and hypoglycemia are the most readily recognized metabolic abnormalities; measures that correct these conditions reverse the adrenal crisis in some instances.

The various neurologic syndromes that result from electrolytic disorders are reviewed by Laureno.

**Central Pontine Myelinolysis**

In 1950, Adams and Victor observed a rapidly evolving quadriplegia and pseudobulbar palsy in a young alcoholic man who had entered the hospital 10 days earlier with symptoms of alcohol withdrawal. Postmortem examination several weeks later disclosed a large, symmetrical, essentially demyelinating lesion occupying the greater part of the base of the pons. Over the next 5 years, three additional cases (two alcoholic patients and one with scleroderma) were studied clinically and pathologically, and in 1959 these four cases were reported by Adams et al under the heading of central pontine myelinolysis (CPM). This term was chosen because it denotes both the main anatomic localization of the disease and its essential pathologic attribute: the remarkably unsystematic dissolution of the sheaths of myelinated fibers and the sparing of neurons. Once attention was focused on this distinctive lesion, many other reports appeared. The exact incidence of this disease is not known, but in a series of 3548 consecutive autopsies in adults, the typical lesion was found in 9 cases, or 0.25 percent (Victor and Laureno).

**Pathologic Features**

One is compelled to define this disease in terms of its pathologic anatomy, because this stands as its most certain feature. Transverse sectioning of the fixed brainstem discloses a grayish discoloration and fine granularity in the center of the basis pontis. The lesion may be only a few millimeters in diameter, or it may occupy almost the entire basis pontis. There is always a rim of intact myelin between the lesion and the surface of the pons. Posteriorly it may reach and involve the medial lemnisci and, in the most advanced cases, other tegmental structures as well. Very rarely, the lesion encroaches on the midbrain, but inferiorly it does not extend as far as the medulla. Exceptionally the extensive pontine lesions may be associated with identical myelinolytic foci symmetrically distributed in the thalamus, subthalamic nucleus, striatum, internal capsule, corpus callosum, amygdaloid nuclei, lateral geniculate body, white matter of the cerebellar folia, and deep layers of the cerebral cortex and subjacent white matter (“extrapontine myelinolysis”; Wright et al).

Microscopically, the fundamental abnormality consists of destruction of the myelinated sheaths throughout the lesion, with relative sparing of the axons and intactness of the nerve cells of the pontine nuclei. These changes always begin and are most severe in the geometric center of the pons, where they may proceed to frank necrosis of tissue. Reactive phagocytes and glial cells are in evidence throughout the demyelinating focus, but oligodendrocytes are depleted. Signs of inflammation are conspicuously absent.

This constellation of pathologic findings provides easy differentiation of the lesion from infarction and the inflammatory demyelinations of multiple sclerosis and postinfectious encephalomyelitis. Microscopically, the lesion resembles that of Marchiafava-Bignami disease (Chap. 41), with which it is rarely associated.

In the chronic alcoholic, Wernicke disease is not infrequently associated with CPM, but the lesions bear no resemblance to one another in terms of topography and histology.

**Clinical Features**

Central pontine myelinolysis occurs only sporadically, with no hint of a genetic factor. The two sexes are affected equally, and the patients do not fall into any one age period. Whereas the cases first reported had occurred in adults, there are now many reports of the disease in children, particularly in those with severe burns (McKee et al).
The outstanding clinical characteristic of CPM is its invariable association with some other serious, often life-threatening disease. In more than half the cases, it has appeared in the late stages of chronic alcoholism, often in association with Wernicke disease and polyneuropathy. Among the other medical conditions and diseases with which CPM has been conjoined are chronic renal failure being treated with dialysis, hepatic failure, advanced lymphoma, carcinoma, cachexia from a variety of other causes, severe bacterial infections, dehydration and electrolyte disturbances, acute hemorrhagic pancreatitis, and pellagra. The changes in serum sodium concentration, with which the process is closely aligned, are discussed below.

In many patients with CPM there are no symptoms or signs that betray the pontine lesion, presumably because it is so small, extending only 2 to 3 mm on either side of the median raphe and involving only a small portion of the corticopontine or pontocerebellar fibers. In others, the presence of CPM is obscured by coma from a metabolic or other associated disease. Probably only a minority of cases, exemplified by the first patient observed by Adams, Victor, and Mancall, are recognized during life. In this patient, a serious alcoholic with delirium tremens and pneumonia, there evolved, over a period of several days, a flaccid paralysis of all four limbs and an inability to chew, swallow, or speak (thus simulating occlusion of the basilar artery). Pupillary reflexes, movements of the eyes and lids, corneal reflexes, and facial sensation were spared. In some instances, however, conjugate eye movements are limited, and there may be nystagmus. With survival for several days, the tendon reflexes become more active, followed by spasticity and extensor posturing of the limbs on painful stimulation. Some patients are left in a state of mutism and paralysis with relative intactness of sensation and comprehension (pseudocoma, or locked-in syndrome).

The capacity of CT scanning but especially MRI to visualize the pontine lesion has greatly increased the frequency of premortem diagnoses. The MRI discloses a characteristic “bat wing” lesion of the basis pontis in typical cases (Fig. 40-4), although this change may become evident only several days after the onset of symptoms. Brainstem auditory evoked responses also disclose the lesions that encroach upon the pontine tegmentum.

Variants of this syndrome are being encountered with increasing frequency. Two of our elderly patients, with confusion and stupor but without signs of corticospinal or pseudobulbar palsy, recovered; however, they were left with a severe dysarthria and cerebellar ataxia lasting many months. After 6 months, these patients’ nervous system function was essentially restored to normal. In reference to the pathogenesis of this lesion, originally both patients had serum Na levels of 99 meq/L, but information about the rate of correction of serum Na was not available. Another of our patients developed a typical locked-in syndrome after the rapid correction of a serum sodium of 104 meq/L. He showed large symmetrical lesions of the frontal cortex and underlying white matter but no pontine lesion (by MRI).

Brainstem infarction due to basilar artery occlusion may be simulated by pontine myelinolysis. Sudden onset or step-like progression of the clinical state, asymmetry of long tract signs, and more extensive involvement of tegmental structures of the pons as well as the midbrain and thalamus are the distinguishing characteristics of vertebrobasilar thrombosis or embolism. On MRI studies, an evolving infarction shows signal changes on diffusion-weighted imaging, while the primary finding in CPM is brightness of the T2-weighted images. Massive pontine demyelination in acute or chronic relapsing multiple sclerosis rarely produces a pure basis or pons syndrome. The clinical features and context provide the clues to correct diagnosis.

**Etiology and Pathogenesis** Nutritional deficiency is a commonly invoked cause of CPM, because it is observed so frequently in chronic wasting diseases and particularly in malnourished alcoholics, often in association with Wernicke disease. Nevertheless, there are many cases in which a nutritional factor cannot be incriminated. As mentioned in the section on hyponatremia, the rapid correction of the serum sodium to normal or higher than normal levels is an almost obligate antecedent of CPM. Significant hyponatremia, always less than 130 meq/L and usually much less, has been present in all our patients and in all the patients reported by Burcar and colleagues and by Karp and Laureno. The importance of serum sodium in the pathogenesis of this disease was demonstrated experimentally by Laureno. Dogs were made severely hyponatremic (100 to 115 meq/L) by repeated injections of vasoressin and intraperitoneal infusions of water. The hyponatremia was corrected rapidly by infusion of hypertonic (3%) saline, following which the dogs developed a spastic quadriaparesis and showed, at autopsy, pontine and extrapontine lesions that were indistinguishable in their distribution and histologic features from those of the human disease. Hyponatremia alone or slowly corrected hyponatremia (<15 meq/dL in the initial 24 h) did not produce the disease.

McKee and colleagues have adduced evidence that extreme serum hyperosmolality and not necessarily the rapid correction or overcorrection of hyponatremia is the important factor in the pathogenesis of CPM. They found the characteristic pontine and extrapontine lesions in 10 of 139 severely burned patients who were examined after death. Each of their patients with CPM had suffered a prolonged, nonterminal episode of severe serum hyperosmolality,
which coincided temporally with the onset of the lesion, as judged by its histologic features. Hyponatremia was not present, and no other independent factors—such as hypernatremia, hyperglycemia, or azotemia—correlated with the development of CPM. These are valid observations but they cannot easily be reconciled with the usual circumstances of rapid correction of hyponatremia.

At the present time all one can say is that specific myelinated regions or zones of the brain, most often the center of the base of the pons, have a special susceptibility to some acute metabolic fault (mostly rapid correction or overcorrection of hyponatremia, and possibly hyperosmolality).

Therapeutic guidelines for the correction of hyponatremia are still being considered. Karp and LaRonen, on the basis of their experience and that of Sterns et al., have suggested that the hyponatremia be corrected by no more than 10 meq/L in the initial 24 h and by no more than about 21 meq/L in the initial 48 h.

**ACQUIRED METABOLIC DISEASES PRESENTING AS PROGRESSIVE EXTRAPYRAMIDAL SYNDROMES**

These syndromes are usually of mixed type—i.e., they include a number of basal ganglionic and cerebellar symptoms in various combinations and may emerge as part of an acquired chronic hepatocerebral degeneration or chronic hypoparathyroidism or as sequelae to kernicterus, hypoxic, or hypoglycemic encephalopathy. The basal ganglionic-cerebellar symptoms that result from severe anoxia and hypoglycemia have been described in the preceding section and in Chaps. 4 and 5. Kernicterus is considered on page 878, with the neurologic diseases of infancy and childhood, and calcification of the basal ganglia and cerebellum (due to chronic parathyroid deficiency) on page 834, with the inherited metabolic disorders, and further on in this chapter. It must be realized, however, that acquired hypoparathyroidism may also lead to calcification of the basal ganglia. We have also observed choreiform movements in patients with hyperosmolar coma and with severe hyperthyroidism, ascribed by Weiner and Klawans to a disturbance of dopamine metabolism.

**Chronic Acquired (NonWilsonian) Hepatocerebral Degeneration**

Patients who survive an episode or several episodes of hepatic coma are sometimes left with residual neurologic abnormalities such as tremor of the head or arms, asterixis, grimacing, choreic movements and twitching of the limbs, dysarthria, ataxia of gait, or impairment of intellectual function. These symptoms may worsen with repeated attacks of stupor and coma. In a few patients with chronic liver disease, permanent neurologic abnormalities become manifest in the absence of discrete episodes of hepatic coma. In either circumstance, these patients deteriorate neurologically over a period of months or years. Examination of their brains discloses foci of destruction of nerve cells and other parenchymal elements in addition to a widespread transformation of astrocytes—changes very much similar to those of Wilson disease.

Probably the first to describe this acquired type of hepatocerebral degeneration was van Woerkom (1914), whose report appeared only 2 years after Wilson’s classic description of the familial form. A full account of the cases reported since that time as well as of our own extensive experience with this disorder is contained in the article by Victor, Adams, and Cole, listed in the References.
acute hepatic encephalopathy will cause a recession of many of the chronic neurologic abnormalities—not completely, but to an extent that permits the patient to function better.

It appears that the parenchymal damage in the chronic disease simply represents the most severe degree of a pathologic process that in its mildest form is reflected in an astrocytic hyperplasia alone.

Kernicterus

Kernicterus, formerly a common cause of congenital choreothetosis, has now been virtually eliminated. It is discussed on page 878.

Hypoparathyroidism

This condition and pseudohypoparathyroidism (page 834) were mentioned in relation to the hereditary metabolic disorders. In the past, the usual cause of hypoparathyroidism was surgical removal of the parathyroid glands during subtotal thyroidectomy, although there were always idiopathic cases as well. With the more widespread use of radiation and drug therapy for thyroid disease, the number of surgically created cases has become small in proportion to nonsurgical ones. The latter may occur in pure form, presumably as an agenesis of the parathyroid glands, with unmeasurable levels of parathyroid hormone in the blood, or as part of the DiGeorge syndrome of agenesis of the thymus and parathyroid glands, organs that are embryologically derived from the third and fourth branchial clefts. Hypoparathyroidism is also part of a familial disorder in which a deficiency of thyroid, ovarian, and adrenal function, pernicious anemia, and other defects are combined, based presumably on a derangement of autoimmune mechanisms. Other causes are intestinal malabsorption, pancreatic insufficiency, and vitamin D deficiency. In all instances the low levels of parathormone and normal responses to injected hormone permit the recognition of a primary defect of the parathyroid glands and distinguish it from all other conditions in which there is hypocalcemia and hyperphosphatemia.

The clinical manifestations, mainly attributable to the effects of hypocalcemia, are tetany, paresthesias, muscle cramps, laryngeal spasm, and convulsions. Children with this disease may be irritable and show behavioral changes. In adults with chronic hypocalcemia, calcium deposits occur in the basal ganglia, dentate nuclei, and cerebellar cortex. In such patients we have observed unilateral tremor, a restless choreoathetotic hand, bilateral rigidity, slowness of movement and flexed posture resembling Parkinson disease, and ataxia of the limbs and gait—in various combinations. Interestingly, the multiple skeletal and developmental abnormalities that characterize both pseudo- and pseudo-pseudohypoparathyroidism (short stature, round face, short neck, stocky body build, shortening of metacarpal and metatarsal bones and phalanges from premature epiphyseal closure) are rarely seen in pure hypoparathyroidism.

A similar deposition of ferrocalc in the walls of small blood vessels of the lenticular and dentate nuclei and to a lesser extent in other parts of the brain is a common finding in normal older individuals (Fahr disease). It also occurs in animals. Occasionally it reaches a degree of severity that destroys striatal or dentate neurons. In such cases, films of the skull and particularly CT scans will reveal the deposits. Cases of Fahr disease have been reported for years (Fig. 37-9, page 835), but the cause of the deposits is unknown. Apparently some protein in the capillary walls has an avidity for both calcium and iron.

ACQUIRED METABOLIC DISEASES PRESENTING AS CEREBELLAR ATAXIA

Cerebellar Ataxia Associated with Myxedema

The association of myxedema and cerebellar ataxia has been mentioned sporadically in medical writings since the latter part of the nineteenth century. Interest in this problem was revived in more recent years by Jellinek and Kelly, who described 6 such cases. All of them showed an ataxia of gait; in addition, some degree of ataxia of the arms and dysarthria were present in 4 instances, and nystagmus in 2. Cremer and coworkers have reported a similar clinical experience, based on a study of 24 patients with either primary or secondary hypothyroidism.

There have been only a few reports of the pathologic changes, and these are far from satisfactory. The myxedematous patient described by Price and Netsky had also been a serious alcoholic, and the clinical signs (ataxia of gait and of the legs) and pathologic changes (loss of Purkinje cells and gliosis of the molecular layer, most pronounced in the vermis) could be distinguished from those due to alcoholism and malnutrition. Scattered throughout the nervous system of their case were unusual glycogen-containing bodies, similar but not identical to corpora amylacea. These structures, designated myxedema bodies by Price and Netsky, were also observed in the cerebellar white matter of a second case of myxedema; there were no other neuropathologic changes, however, and this patient had shown no ataxia during life. It is difficult to know whether these peculiar bodies have anything to do with myxedema. If they do, it should be possible to demonstrate them in more than two cases. We have not seen them in one carefully studied case of myxedema, nor have they been described by others. Thyroid medication corrects the defect in motor coordination, raising doubt as to whether it could be based on a visible structural lesion.

The various causes of cerebellar ataxia, including the metabolic ones, are summarized in Table 5-1 (page 78). Notable metabolic disorders, some heritable, in which ataxia may be a leading manifestation include GM1 gangliosidosis, possibly sprue (discussed below), and a large number of neonatal and infantile aminoacidopathies.

Effects of Hyperthermia on the Cerebellum

The damaging effects of hyperthermia, like those of anoxia, involve the brain diffusely. In the case of hyperthermia, however, the changes are disproportionately severe in the cerebellum. The acute manifestations of profound hyperthermia are coma and convulsions, frequently complicated by shock and renal failure. Patients who survive the initial stage of the illness frequently show signs of widespread cerebral affection, such as confusion and pseudobulbar and spastic paralysis. These abnormalities tend to resolve gradually, leaving the patient with a more or less pure disorder of cerebellar function.

The most extensive account of the pathologic effects of hyperthermia is that of Malamud and colleagues. These authors studied 125 fatal cases of heat stroke, but their observations are prob-
ably applicable to hyperthermia of other types. In patients who survived less than 24 h, the changes consisted mainly of a loss of some of the Purkinje cells and swelling, pyknosis, and disintegration of those that remained. In cases surviving beyond 24 h, there was almost complete degeneration of the Purkinje cells, with gliosis throughout the cerebellar cortex as well as degeneration of the dentate nuclei. The changes in the cerebellar cortex were equally pronounced in the hemispheres and vermis. The unanswered question is whether high temperature alone is an adequate cause or whether it must be combined with hypoxia and ischemia. It is of interest that we have not seen this syndrome in patients with infective fevers, malignant hyperthermia, or the malignant neurelptic syndrome—either the neuropathologic changes or the clinical cerebellar syndrome in survivors.

Cerebellar Syndromes Associated with Celiac Disease (Sprue, Gluten Enteropathy)

Most often, the neurologic association with this disease has been a peripheral neuropathy as described on page 1142. In addition, a progressive cerebellar ataxia of gait and limbs, sometimes with polymyoclonus in association with a gluten-sensitive enteropathy, has been the subject of several reports. The underlying cause is an intestinal allergy to gluten in wheat that produces a villus atrophy of the intestinal mucosa. It has been called celiac disease of children and sprue in adults. Between 0.5 and 1 percent of the Caucasian population are affected with the intestinal disorder. The classic features are diarrhea and malabsorption but many individuals are asymptomatic (see also page 993).

The neurologic disorder may appear several years after onset of the enteropathy and, in addition to ataxia, usually includes signs of peripheral neuropathy and, in some cases, myelopathy and encephalopathy (dementia) or psychiatric symptoms (Hallert et al). A rare spinocerebellar syndrome has been described by Cooke and Smith. According to Finelli et al, neurologic abnormalities occur in approximately 10 percent of cases of adult celiac sprue. This subject has been reviewed by Bhatia et al and extensively by Hadjivassiliou et al. The latter authors emphasize the frequent occurrence of ataxia in patients with gluten sensitivity (indicated by circulating antibodies to gliadin (which is another term for gluten) and more specifically, antibodies to transglutaminase and endomyosum) but, curiously, often without overt signs of bowel disease. There is also an association of sprue in more than 90 percent of patients with the HLA DQ2 and DQ8 genotype. The few cases that have come to autopsy have shown severe cerebellar atrophy, a finding that may also be disclosed by MRI. Hadjivassiliou et al observed lymphocytic infiltration and perivascular cuffing in the cerebellar cortex and peripheral nerves in one autopsied case but not in another, changes that they took to represent immunologic injury to these parts.

Despite these associations, some authors have been skeptical of a “gluten ataxia” (see the editorial by Cross and Golumbek and the contrary case for a valid connection by Hadjivassiliou and colleagues, 2002). Reports of improvement in the ataxia following the institution of a gluten-free diet have been conflicting. The situation is further complicated by the finding that antigliadin antibodies (which are not autoantibodies but are directed against gluten, the offending agent), while not specific for celiac disease, do correspond to the presence of neurologic manifestations (ataxia and neuropathy); however, the more specific antiendomysium and antitransglutaminase autoantibody markers of sprue have little apparent relation to the presence of neurologic disease. Even more confusing is the claim that half of these patients will have one or another antibody but no clinical enteropathy, making it necessary to perform a small bowel biopsy to detect villous atrophy. A gluten-free diet is necessary, not only to reduce the enteropathy, if present, but also to reduce the chances of the later development of a bowel lymphoma. The medical issues relating to celiac disease and the use of antibody tests and bowel biopsy are reviewed by Farrell and Kelly.

We have sought evidence by antibody testing and bowel biopsy of sprue in numerous patients with an ataxia of obscure origin and have only once found it. Nevertheless, the evidence presented in the writings of several authors, particularly Hadjivassiliou, suggest that sprue may underlie some cases of subacute ataxia in adults. Always to be considered in the differential diagnosis is paraneoplastic cerebellar degeneration and Creutzfeldt-Jakob disease.

Vitamin E deficiency may induce a similar syndrome with features of spinocerebellar dysfunction (see page 251).

Jejunoileal bypass operations, in addition to causing a chronic arthropathy, neuropathy, and vasculitic skin lesions, may give rise to an episodic confusion and cerebellar ataxia associated with a lactic acidosis and abnormalities of pyruvate metabolism. Overfeeding and fasting are provocative factors (Dahlquist et al).

ACQUIRED METABOLIC DISEASE PRESENTING AS PSYCHOSIS AND DEMENTIA

The point has been made that milder forms of metabolic diseases that cause episodic stupor and coma, if persistent, may have a protracted course and are then difficult to distinguish from the dementias. Examples are associated with chronic hepatic encephalopathy and the syndromes of chronic hypoglycemia, chronic hypercalcemia (in multiple myeloma, metastatic cancer, and sarcoidosis), and dialysis encephalopathy. Unlike the common types of dementia described in Chap. 21, the acquired metabolic diseases are nearly always accompanied by a degree of drowsiness, inattentiveness, and reduced alertness; i.e., by a clouding of the sensorium and inaccurate perceptions and interpretations—attributes that usually allow an encephalopathic confusional state to be distinguished from a dementia. The presence of asterixis is also an aid. If the onset of the illness is abrupt rather than gradual and of brief duration and if therapy reverses the condition, restoring full mental clarity, the conclusion is justified that one is dealing with a confusional state; but at any one time in the active phase of the disease the clinical state may resemble dementia.

In general hospitals, an episodic confusional state lasting days and weeks in the course of a medical illness or following an operation should always raise the suspicion of one of the aforementioned metabolic derangements (or an adverse effect of a drug). Usually, however, all of these causes can be excluded, and one falls back on a rather unsatisfactory interpretation—that a combination of drugs, fever, toxemia, and unspecifiable metabolic disorders is responsible. The “septic encephalopathy” described earlier in this chapter conforms to this ambiguous notion.

In the endocrine encephalopathies, described below, the clinical phenomena may be even more abstruse, although they are notable because they often take the form of a unique delirium. Confusional states may be combined with agitation, hallucinations, delusions, anxiety, and depression, and the time span of the illness
may be in terms of weeks and months rather than days. Certain aspects of the endocrine psychoses are discussed further on page 1130.

**Cushing Disease and Corticosteroid Psychoses** (See also Chap. 58)

Derangements of mental function that follow administration of adrenocorticotropic hormone (ACTH) and then of corticosteroids have become the prototypes of iatrogenic psychoses. The same disturbances of mental function may accompany Cushing disease (page 1330).

Experience with this neuropsychiatric condition came originally from observations of patients receiving ACTH and later from those receiving prednisone for a variety of neurologic and medical diseases. With low doses there is usually no psychic effect other than a sense of well-being and decreased fatigability. At higher doses (60 to 100 mg/day of prednisone), approximately 10 to 15 percent of patients become overly active, emotionally labile, and unable to sleep. Unless the dose is promptly reduced, there follows a progressive shift in mood, usually toward euphoria and hypomania—but sometimes toward depression and then inattentiveness, distractibility, and mild confusion. The EEG becomes less well modulated and slower frequencies appear. A minority of patients experience frank hallucinations and delusions, giving the illness a truly psychotic stamp and raising the suspicion of schizophrenia or manic-depressive disease. In nearly all instances, however, this mixture of confusion and mood change, in association with disordered cognitive function, distinguishes the iatrogenic corticosteroid psychosis. Withdrawal of medication relieves the symptoms, but full recovery may take several days to a few weeks, at which time, as with all confusional states and deliria, the patient has only a fragmentary recollection of events that occurred during the illness.

The neurologic basis of this condition is poorly understood. Its attribution to premorbid personality traits or a disposition to psychiatric illness lacks convincing documentation. Part of the difficulty is the lack of knowledge of the role of these endocrine agents in normal cerebral metabolism. We have only incomplete knowledge, for example, as to how they act to reduce the volume of the edematous cerebral tissue around a tumor or to shrink the brain. Critical studies of cellular or subcellular metabolism and morphologic changes are lacking. “Cerebral atrophy” (ventricular enlargement and sulcal widening) has been shown radiologically in patients with Cushing disease and after a prolonged period of corticosteroid therapy, but the basis of this change also is unclear (Momose et al.). In most cases of brain shrinkage, withdrawal of steroids has led to a reduction in ventricular size, as documented by repeated CT scans.

In patients with Cushing disease due to adrenal or basophilic pituitary tumors, mental changes suggestive of dementia and enlarged ventricles are not unusual. Here again there is a peculiar combination of mood changes and impaired cognitive function. A frank psychosis may occur. This condition is described more completely in Chap. 58 and the attendant proximal myopathy, in Chap. 51.

**Thyroid Encephalopathies**

**Hyperthyroidism** The neurology of thyrotoxicosis has proved to be elusive. Allusions to psychosis are frequent in the medical literature, and thyrotoxic patients have been observed with mental confusion, seizures, manic or depressive attacks, and delusions. Action tremor is almost universal, and chorea occurs occasionally in various combinations with muscular weakness and atrophy, periodic paralysis, and myasthenia. In descriptions of abnormal movements, it is often not clear whether it was chorea, tremor, myoclonus, or just fidgetiness that was observed. Treatment of the hyperthyroidism gradually restores the mental state to normal, leaving one with no explanation of what had happened to the CNS.

Thyroid crisis or “storm” refers to a fulminant increase in the symptoms and signs of thyrotoxicosis—extreme restlesslessness, tachycardia, fever, vomiting, and diarrhea—leading to delirium or coma. In the past, this was a not uncommon postoperative event in patients poorly prepared for thyroid surgery. Now it is seen mainly in patients with inadequately treated or untreated thyrotoxicosis complicated by serious medical or surgical illness.

**Hashimoto Encephalopathy** Brain and associates described an encephalopathy consisting of confusion, altered consciousness, and prominent myoclonus in patients with Hashimoto disease. The details of this curious syndrome were further elaborated by Shaw and colleagues and by Chong. Some cases have had a relapsing course over months or years. It is important to note that most have had normal thyroid function. There are in these cases, however, high titers of several antithyroid antibodies, particularly antibodies against thyroid peroxidase and thyroglobulin; some affected individuals have more than one such antibody. Ferracci and colleagues have found evidence of the production of these antibodies in the nervous system and of their presence in spinal fluid. One must be cautious, however, in interpreting the presence of antithyroid antibodies in the blood, since they are detected in many people without an encephalopathy, particularly older women, and in two-thirds of patients with Graves disease.

The most commonly observed syndrome is of confusion or stupor accompanied by multifocal myoclonus. Seizures—including myoclonic and rarely nonconvulsive status epilepticus—hemiparesis, ataxia, psychosis, and unusual tremors, including those of the palate, have been reported in individual cases. Some of the reports have included children. Often there are others members of the family with a different autoimmune disease. It has been the myoclonic aspect of the encephalopathy, a feature of all of our observed cases, that has led to consideration of this diagnosis. It is not uncommon for such cases to be mistaken for Creutzfeldt-Jakob disease (subacute spongiform encephalopathy). Early descriptions of the illness included a pleocytosis of the spinal fluid and white matter lesions, but we have not noted these abnormalities. What limited pathology there is, in a case studied after 5 months of illness, has shown only nonspecific activation of microglial cells (Perrot et al.).

**Treatment** The encephalopathic symptoms and high titers of antithyroid antibodies respond well to steroid therapy (see Chong). In the case reported by Newcomer and associates, a rapid reversal of thyrotoxic coma (and corticospinal signs) was effected by plasma exchange, in parallel with a reduction in T₄ and T₃ levels, and similar results have been reported by Boers and Colebatch. The circulating antibodies and the response to corticosteroids and plasma exchange implicate an immune pathogenesis, perhaps similar to paraneoplastic “limbic encephalitis” (see page 585) and to lupus, as well as to the rare encephalitis that may accompany thymoma.

**Hypothyroidism** As a rule, the myxedematous patient is slow to react and psychomotor activity is reduced; but only in exceptional
cases have we noted a significant change in cerebral function. When such a change has been observed, we have been especially impressed with drowsiness, inattentiveness, and apathy. In two cases observed by our colleagues, the somnolence was so extreme that the patients could not stay awake long enough to be fed or examined. They were in a state of hypothermic stupor but exhibited no other neurologic abnormality. The extreme somnolence can be reversed within a few days by thyroid medication.

Hypothyroidism is associated with a number of distinctive myopathic disturbances, which are discussed in Chap. 51. The ataxia and peripheral neuropathy that are sometimes observed in patients with myopathic disturbances were described earlier and in Chap. 46.

Cretinism and Neonatal Myxedema This form of severe hypothyroidism, occurring during intrauterine life (hypothyroidism in mother and fetus) or postnatally as a hereditary or acquired thyroid disease, is probably the most frequent and potentially preventable and correctable metabolic mental defect in the world. A perspective on its relative frequency among neonatal metabolic disorders is given in Table 37-1. Although the condition is most common in goitrous regions where there is a lack of iodine, it may also be due to any of several genetically determined defects in thyroxin synthesis that have come to light in recent years (Vassart et al). In areas of endemic cretinism, additional factors may be operative, such as the widespread ingestion of cassava, which contains a toxic goitrogen that inhibits the uptake of iodine by the thyroid.

As a rule, the symptoms and signs of congenital thyroid deficiency are not recognizable at birth but become apparent only after a few weeks; more often the diagnosis is first made between the sixth and twelfth months of life. Physiologic jaundice tends to have been severe and prolonged (up to 3 months), and this, along with widening of the posterior fontanelle and mottling of the skin, should raise suspicion of the disease.

In general, two types of early life hypothyroidism are recognized—sporadic and endemic. The sporadic type occurs occasion-ally in developed countries (less than once in 4000 births) and is a consequence of a congenital metabolic or anatomic disorder of the thyroid gland. At birth, the gland is either absent or represented by cysts, indicating a failure of development or a destructive lesion. In the sporadic form, in the latter part of the first year, stunting of growth and delay in psychomotor development become evident. Untreated, the child is severely retarded but placid and good-natured; such children sleep contentedly for longer periods than normal children. Sitting, standing, and walking are delayed. Movements are slow, and if tendon reflexes can be obtained, their relaxation time is clearly delayed. The body temperature is low, and the extremities are cold and cyanotic. Although the head is small, the fontanelles may not close until the sixth or seventh year, and there is delayed ossification. This type of hypothyroidism is preventable by treatment with thyroid hormone.

Endemic cretinism is most common in developing countries, with an estimated incidence in some areas of 5 to 15 percent. Stanley and DeLong and colleagues, on the basis of epidemiologic sur-veys in Ecuador, Zaire, and western China, have distinguished two forms of endemic cretinism—neurologic and myxedematous. The occurrence of the two different types is governed by the timing, duration, and severity of the iodine deficiency (Thilly et al). The neurologic form of endemic cretinism is characterized by varying degrees of deaf-mutism or lesser degrees of hearing loss, dysarthria, proximal limb and truncal rigid-spastic motor disorder involving mainly the lower extremities, and mental deficiency of a characteristic type. In the most severely affected, there is also strabismus, kyphoscoliosis, underdevelopment of leg muscles, and frontal lobe release signs. Bone age, head size, and height are normal and there are none of the coarse facial features of the myxedematous form. In the so-called myxedematous form of endemic cretinism, short stature, microcephaly, coarse facial features, and retarded psychomotor development are the main features. There is no deafness or spastic rigidity of the limbs. In typical instances, the face is pale and puffy; the skin dry; the hair coarse, scanty, and dry; the eyelids thickened; the thickened lips parted by the enlarged tongue; the forehead low; and the base of the nose broad. There are fat pads above the clavicles and in the axillae. The abdomen is protuberant, often with an umbilical hernia, and the head is small—a physical appearance that prompted William Boyd to remark: “What was intended to be created in the image of God has turned out to be the pariah of nature, all for the want of a little thyroid.”

DeLong and others attribute neurologic cretinism to a lack of available iodine in the mother and fetus during the second and third trimesters of pregnancy; neither mother nor fetus elaborate thyroxine. The first and part of the second trimester developmental period, which does not require iodine or thyroxine, passes normally and the general morphology of the brain is normal. It is during the latter part of the second trimester, when the cochleas and the neuronal population of the cerebral cortex and basal ganglia are forming, that these structures suffer irreparable damage. The effects of this midfetal hypothyroidism and iodine deficiency cannot be corrected by giving thyroid hormone at birth and thereafter. It can be prevented only by providing iodine therapy to the mother before and during the first trimester of pregnancy (Cao et al). The myxedematous form of cretinism is more likely to occur from lack of thyroid hormone in the late second and the third trimesters.

The mental defect ranges from apathy and absence of social interaction to an alert, cooperative state, but a backwardness in higher-order thinking and verbal facility is always evident. Reten-tive memory and apperception are commensurate with overall intellec-tual competence as judged by the level of mental associations and capacity for abstract thought. The status of the thyroid gland varies; among neurologic cretins, about half are goitrous or have palpable glands; in the rest, the glands are atrophied; practically all the myxedematous cretins are athyreotic. Although typical examples of neurologic and myxedematous hypothyroidism are readily distinguished, both types may exist in the same endemic area, and the stigmata of both forms may be recognized in the same individual. The QRS complex of the ECG is of low voltage; the EEG is slower than normal, with less alpha activity; the CSF contains an excess of protein (50 to 150 mg/dL); and the serum T4 and T3, protein-bound iodine, and radioactive iodine uptake are all sub-normal. Serum cholesterol is increased (300 to 600 mg/dL).

At autopsy the brain of neurologic cretinism, though small, is normally formed, with all central and brainstem structures and corti-cal sulcation intact. A reduction in number of nerve cells was described by Marinesco, especially in the fifth cortical layer, but others have not confirmed this finding. The use of Golgi and other silver techniques has shown decreased interneuronal distances (packing density is increased, as in the immature cortex) where there is a deficiency of neuropil. The latter change is due to a poverty of dendritic branchings and crossings, and presumably there is a decrease of the synaptic surfaces of cells (Eayrs). Thyroid hormone appears to be essential, not for neuronal formation and migration but for dendritic-axonal development and organization.

There is substantial evidence that the administration of iodi-
nated oil to hypothyroid women before and during the first trimester of pregnancy prevents sporadic and endemic cretinism, as already noted. Treatment begun during the second trimester protects the fetal brain to a varying degree. Treatment that is started after the beginning of the third trimester does not improve the neurologic status, although head growth and statural development may improve slightly (Cao et al). In sporadic cretinism, if the condition is recognized early, say at birth, and treated consistently with thyroid hormones, statural and mental development can be stimulated to normal or near-normal levels. The extent of recovery depends on the severity and duration of intrauterine hypothyroidism, i.e., its duration before treatment was begun and the adequacy of therapy. In most patients, some degree of mental deficiency persists throughout life.

“Pancreatic Encephalopathy” This term was introduced by Rothermich and von Haam in 1941 to describe what they considered to be a fairly uniform clinical state in patients with acute abdominal symptoms referable to pancreatic disease, mainly pancreatic encephalopathy. This term was applied to a depressive illness that seems to occur with disproportionate frequency before the symptoms of a pancreatic cancer become apparent. Also notable in our experience are numerous cases of pancreatic cancer and sequential cerebral emboli from nonbacterial thrombotic (marantic) endocarditis.

The status of pancreatic encephalopathy, in the authors’ opinion, is uncertain. Pallis and Lewis also express reservations and suggest that before such a diagnosis can be seriously entertained in a patient with acute pancreatitis, one must exclude delirium tremens, shock, renal failure, hypoglycemia, diabetic acidosis, hyperosmolality, and hypocalcemia—or any one of which may complicate the underlying disease. Other cases conform to the encephalopathy of multiorgan failure, discussed earlier.

CHAPTER 41

DISEASES OF THE NERVOUS SYSTEM DUE TO NUTRITIONAL DEFICIENCY

Among nutritional disorders, those of the nervous system occupy a position of special interest and importance. The early studies of beriberi, at the turn of the century, were largely responsible for the discovery of thiamine, and consequently for the modern concept of deficiency disease. A series of notable achievements in the science of nutrition followed the discovery of vitamins. Despite such progress, a number of diseases due to nutritional deficiency—and particularly those of the nervous system—continue to represent a worldwide health problem of serious proportions. In Far Eastern communities, where the diet consists mainly of highly milled rice, there is still a significant incidence of beriberi. In other underdeveloped countries, deficiency diseases are endemic, the result of chronic dietary deprivation. And the ultimate effects on the nervous system of mass starvation, involving large portions of the African continent, is alarming to contemplate.

It comes as a surprise to many physicians that deficiency diseases still occur in the United States and other parts of the western world. To a large extent this is attributable to the prevalence of alcoholism. Relatively less common causes are dietary faddism and impaired absorption of dietary nutrients (which occurs in patients with celiac sprue, pernicious anemia, or surgical exclusion of portions of the gastrointestinal tract—for treatment of obesity or for other reasons). Finally, there are the deficiencies induced by the use of vitamin antagonists or certain drugs, such as isonicotinic acid hydrazide (INH), which is used in the treatment of tuberculosis and interferes with the enzymatic function of pyridoxine.

**General Considerations**

The term deficiency is used throughout this chapter in its strictest sense to designate disorders that result from the lack of an essential nutrient or nutrients in the diet or from a conditioning factor that increases the need for these nutrients. The most important of these nutrients are the vitamins, more specifically, members of the B group—thiamine, nicotinic acid, pyridoxine, pantothenic acid, riboflavin, folic acid, and cobalamin (vitamin B_12_). Most deficiency diseases cannot be related to the lack of a single vitamin (subacute combined degeneration of the cord, due to vitamin B_12_ deficiency, is an notable exception). Usually the effects of several vitamin deficiencies can be recognized. This statement should not obscure the fact that particular manifestations of deficiency disease (e.g., the ocular palsies of Wernicke disease) are indeed related to a deficiency of a specific nutrient, nor should it diminish the need to identify such relationships.

Nutritional diseases of the nervous system are not simply a matter of vitamin deprivation. Practically always, the general signs of undernutrition, such as circulatory abnormalities and loss of subcutaneous fat and muscle bulk, are associated. Furthermore, a total lack of vitamins, as in starvation, is rarely associated with the classic deficiency syndromes of beriberi or pellagra; a certain amount of food is necessary to produce them. An excessive intake of carbohydrate relative to the supply of thiamine favors the development of a thiamine deficiency state. All deficiency diseases, including those of the nervous system, are influenced by factors such as exercise, growth, pregnancy, and infection, which increase the need for essential nutrients, and by disorders of the liver and the gastrointestinal tract, which may interfere with the synthesis and absorption of these nutrients.

As already mentioned, alcoholism is an important factor in the causation of nutritional diseases of the nervous system. Alcohol acts mainly by displacing food in the diet but also by adding carbohydrate calories (alcohol is burned almost entirely as carbohydrate), thus increasing the need for thiamine. There is some evidence as well that alcohol impairs the absorption of thiamine and other vitamins from the gastrointestinal tract.

In infants and young children, a reduction of protein and caloric intake (so-called protein-calorie malnutrition, or PCM) has a devastating effect on body growth. Whether or not PCM also hinders the growth of the brain, with consequent effects on intellectual and behavioral development, cannot be answered as readily. The data bearing on this matter are discussed in the last part of the chapter.

While conceding that deficiency diseases of the nervous system may occur in pure form, and are so described in the following pages, more often the symptoms of other deficiencies are added; i.e., the deficiency diseases occur in various combinations. Characteristic also of the nutritional diseases is the potential for involvement of both the central and peripheral nervous systems, an attribute shared only with certain metabolic disorders.

The following deficiency diseases are discussed in this chapter:

1. Wernicke disease and Korsakoff psychosis (thiamine deficiency)
2. Nutritional polyneuropathy (neuropathic beriberi, probably associated with thiamine deficiency)
3. Deficiency amblyopia (nutritional optic neuropathy; “tobacco-alcohol” amblyopia)
4. Pellagra with remarks on spinal spastic ataxia and encephalopathy (nicotinic acid [niacin] deficiency]
5. The syndrome of amblyopia, painful neuropathy, and genital dermatitis (so-called Strachan syndrome)
6. Subacute combined degeneration of the spinal cord (vitamin B_12_ deficiency)
7. Neurologic disorders due to a deficiency of pyridoxine and possibly other B vitamins (pantothenic acid, riboflavin, folic acid)
8. Inherited disorders of vitamin E metabolism

In addition, attention is drawn to several distinctive neurologic disorders in which nutritional deficiency may play a role, although this has not been proved: (1) “alcoholic” cerebellar degeneration,
(2) primary degeneration of the corpus callosum (Marchiafava-Bignami disease), and (3) central pontine and extrapontine myelolysis, which is more closely aligned with the rapid correction of hyponatremia, as discussed in the previous chapter. Also, some comments are made about PCM, the neurologic disorders consequent upon intestinal malabsorption, and the rare hereditary vitamin-responsive diseases. Deficiencies of trace elements, because of their rarity, are not discussed; only iodine deficiency (cretinism) is of much importance in humans, and it was discussed in the prior chapter on acquired metabolic diseases. Deficiencies of other essential dietary elements have been reviewed by Fowden and colleagues.

The Wernicke-Korsakoff Syndrome

Wernicke disease and the Korsakoff amnesic state are common neurologic disorders that have been recognized since the 1880s. Wernicke disease (originally called polioencephalitis hemorrhagica superioris) is characterized by nystagmus, abducens and conjugate gaze palsies, ataxia of gait, and mental confusion. These symptoms develop acutely or subacutely and may occur singly or, more often, in various combinations. Wernicke disease is due specifically to a deficiency of thiamine and is observed mainly though far from exclusively in alcoholics.

The Korsakoff amnesic state (Korsakoff psychosis) is a unique mental disorder in which retentive memory is impaired out of proportion to all other cognitive functions in an otherwise alert and responsive patient. This amnesic disorder, like Wernicke disease, is most often associated with alcoholism and malnutrition, but it may be a symptom of various other diseases that have their basis in lesions of the medial thalami or the intermedial portions of the temporal lobes, such as infarction in the territory of the temporal lobe branches of the posterior cerebral arteries, hippocampal damage after cardiac arrest, third ventricular tumors, or herpes simplex encephalitis. A Korsakoff type of memory disturbance may also follow lesions that involve the basal septal nuclei of the frontal lobe. Transient impairments of retentive memory of the Korsakoff type may be the salient manifestations of temporal lobe epilepsy, concussive head injury, and a unique disorder known as transient global amnesia. The anatomic basis of the Korsakoff amnesic syndrome is discussed further in Chap. 21.

In the alcoholic, nutritionally deficient patient, Korsakoff amnesia is usually associated with and follows the occurrence of Wernicke disease. Stated another way, Korsakoff psychosis is the psychic manifestation of Wernicke disease. For this reason and others elaborated below, the term Wernicke disease or Wernicke encephalopathy should be applied to a symptom complex of ophthalmoplegia, nystagmus, ataxia, and an acute apathetic-confusional state. If an enduring defect in learning and memory is added, the symptom complex is appropriately designated as the Wernicke-Korsakoff syndrome.

**Historical Note** In 1881, Carl Wernicke first described an illness of sudden onset characterized by paralysis of eye movements, ataxia of gait, and mental confusion. Swelling of the optic discs and retinal hemorrhages were also said to be present. His observations were made in three patients, of whom two were alcoholics and one was a young woman with persistent vomiting following the ingestion of sulfuric acid. In each of these patients there was progressive stupor and coma, culminating in death. The pathologic changes described by Wernicke consisted of punctate hemorrhages, primarily affecting the gray matter around the third and fourth ventricles and aqueduct of Sylvius; he considered these changes to be inflammatory in nature and confined to the gray matter, hence his designation “polioencephalitis hemorrhagica superioris.” In the belief that Gâyét had described an identical disorder in 1875, the term Gâyét-Wernicke is used frequently by French authors. Such a designation is hardly justified insofar as the clinical signs and pathologic changes in Gâyét’s patient differed from those of Wernicke’s patients in all essential details.

In a similar vein, a number of early writers, beginning with Magnus Huss in 1852, made casual reference to a disturbance of memory in the course of chronic alcoholism. However, the first comprehensive account of this disorder was given by the Russian psychiatrist S. S. Korsakoff in a series of articles published between 1887 and 1891 (for English translation and commentary, see reference by Victor and Yakovlev). Korsakoff stressed the relationship between “neuritis” (a term used at that time for all types of peripheral nerve disease) and the characteristic disorder of memory, which he believed to be “two facets of the same disease” and which he called “psychosis polyneuritica.” But he also made the points, generally disregarded by subsequent authors, that neuritis need not accompany the characteristic amnesic syndrome and that both disorders could affect nonalcoholic as well as alcoholic patients. His clinical descriptions were remarkably complete and have hardly been surpassed to the present day. It is of interest that the relationship between Wernicke disease and Korsakoff polyneuritic psychosis was appreciated neither by Wernicke nor by Korsakoff. Murawieff, in 1897, first postulated that a single cause was responsible for both. The intimate clinical relationship was established by Bonhoeffer in 1904, who stated that in all cases of Wernicke disease he found neuritis and an amnesic psychosis. Confirmation of this relationship on pathologic grounds came much later (for further details, see the monograph by Victor et al).

**Clinical Features** The incidence of the Wernicke-Korsakoff syndrome cannot be stated with precision, but it has, until relatively recent years, been a common disorder, judging from our experience. At the Cleveland Metropolitan General Hospital, for example, in a consecutive series of 3548 autopsies in adults (for the period 1963 to 1976), our colleague M. Victor found the pathognomonic lesion in 77 cases (2.2 percent). The disease affects males only, for the period 1863 to 1891 (for English translation and commentary, see reference by Victor and Yakovlev). Korsakoff stressed the relationship between “neuritis” (a term used at that time for all types of peripheral nerve disease) and the characteristic disorder of memory, which he believed to be “two facets of the same disease” and which he called “psychosis polyneuritica.” But he also made the points, generally disregarded by subsequent authors, that neuritis need not accompany the characteristic amnesic syndrome and that both disorders could affect nonalcoholic as well as alcoholic patients. His clinical descriptions were remarkably complete and have hardly been surpassed to the present day. It is of interest that the relationship between Wernicke disease and Korsakoff polyneuritic psychosis was appreciated neither by Wernicke nor by Korsakoff. Murawieff, in 1897, first postulated that a single cause was responsible for both. The intimate clinical relationship was established by Bonhoeffer in 1904, who stated that in all cases of Wernicke disease he found neuritis and an amnesic psychosis. Confirmation of this relationship on pathologic grounds came much later (for further details, see the monograph by Victor et al).

Clinical Features The incidence of the Wernicke-Korsakoff syndrome cannot be stated with precision, but it has, until relatively recent years, been a common disorder, judging from our experience. At the Cleveland Metropolitan General Hospital, for example, in a consecutive series of 3548 autopsies in adults (for the period 1963 to 1976), our colleague M. Victor found the pathognomonic lesion in 77 cases (2.2 percent). The disease affects males only slightly more often than females, and the age of onset is fairly evenly distributed between 30 and 70 years. In the past two decades, the incidence of the Wernicke-Korsakoff syndrome has fallen significantly in the alcoholic population. However, it is being recognized with increasing frequency among nonalcoholic patients in a variety of clinical settings, mainly iatrogenic ones.

The triad of clinical features described by Wernicke—ophthalmoplegia, ataxia, and disturbances of mentation and consciousness—is still clinically useful provided that the diagnosis is suspected and the signs are carefully sought. Often the disease begins with ataxia, followed in a few days or weeks by mental confusion; or there may be the more or less simultaneous onset of ataxia, nystagmus, and ophthalmoplegia with or without confusion. Less often, one component of this triad may be the sole manifestation of the disease. Timely treatment with thiamine prevents the permanent amnesic component of the disease. A description of each of the major manifestations follows.

**Oculomotor Abnormalities** The diagnosis of Wernicke disease is made most readily on the basis of the ocular signs. These consist of (1) nystagmus that is both horizontal and vertical, (2) weakness or paralysis of the lateral rectus muscles, and (3) weakness or pa-
ralysis of conjugate gaze. Usually there is some combination of these abnormalities (see Chap. 14).

Next to nystagmus, the most frequent ocular abnormality is lateral rectus weakness, which is bilateral but not necessarily symmetrical and is accompanied by diplopia and internal strabismus. With complete paralysis of the lateral rectus muscles, nystagmus is initially absent in the abducting eyes, but it becomes evident as the weakness improves. The palsy of conjugate gaze varies from merely a nystagmus on extreme gaze to a complete loss of ocular movement in that direction. This applies to both horizontal and vertical movements, abnormalities of the former being somewhat more frequent. Paralysis of downward gaze is an unusual manifestation, but a pattern that simulates internuclear ophthalmoplegia has been seen. In advanced stages of the disease there may be a complete loss of ocular movements, and the pupils, which are otherwise usually spared, may become miotic and nonreacting. Ptosis, small retinal hemorrhages, involvement of the near-far focusing mechanism, and evidence of optic neuropathy occur occasionally, but we and our colleagues have never observed papilledema in this disease. Although the aforementioned ocular signs are highly characteristic of Wernicke disease, disappearance of nystagmus and an improvement in ophthalmoplegiasis within hours or a day or two of the administration of thiamine confirms the diagnosis.

**Ataxia**  
Essentially the ataxia is one of stance and gait; in the acute stage of the disease, it may be so severe that the patient cannot stand or walk without support. Lesser degrees are characterized by a wide-based stance and a slow, uncertain, short-stepped gait; the mildest degrees are apparent only in tandem walking. In contrast to the gross disorder of locomotion is a relative infrequency of limb ataxia and intention tremor; when present, they are more likely to be elicited by heel-to-knee than by finger-to-nose testing. Dysarthric, scanning speech is present only rarely.

**Disturbances of Consciousness and Mentation**  
These are present in some form in all but 10 percent of patients. Several related types of deranged mentation and consciousness can be recognized. By far the most common disturbance is a global confusional state. The patient is apathetic, inattentive, and indifferent to his surroundings. Spontaneous speech is minimal and many questions are left unanswered, or the patient may suspend conversation and drift off to sleep, although he can be aroused without difficulty. Such questions as are answered by the patient betray disorientation in time and place, misidentification of those around him, and an inability to grasp the immediate situation. Many of the patient’s remarks are irrational and lack consistency from one moment to another. If the patient’s interest and attention can be maintained long enough to ensure adequate testing, one finds that memory and learning ability are also impaired. In response to the administration of thiamine or an adequate diet, the patient rapidly becomes more alert and attentive and more capable of taking part in mental testing. Then the most prominent abnormality is one of retentive memory (Korsakoff amnesic state).

About 15 percent of patients show the signs of alcohol withdrawal, i.e., hallucinations and other disorders of perception, confusion, agitation, tremor, and overactivity of autonomic nervous system function. These symptoms are evanescent in nature and usually mild in degree.

Although drowsiness is a common feature of the global confusional state, stupor and coma are rare as initial manifestations of Wernicke disease. However, if the early signs of the disease are not recognized and the patient remains untreated, there occurs a progressive depression of the state of consciousness, with stupor, coma, and death in a matter of a week or two, just as occurred in Wernicke’s original cases. Autopsy series of Wernicke disease are heavily weighted with cases of the latter type, often undiagnosed during life (Harper; Torvik et al.).

Some patients are alert and responsive from the time they are first seen and already show the characteristic features of the Korsakoff amnesic state. In a small number of such patients, the amnesic state is the only manifestation of the syndrome, and no ocular or ataxic signs (other than possibly nystagmus) can be discerned. The memory disorder, which constitutes the chronic and truly crippling feature of the Wernicke-Korsakoff syndrome, is described below.

**The Amnesic State**  
As indicated in Chap. 21, the core of the amnesic disorder is a defect in learning (anterograde amnesia) and a loss of past memories (retrograde amnesia). The defect in learning (memorization) can be remarkably severe. The patient may be incapable, for example, of committing to memory three simple facts (such as the examiner’s name, the date, and the time of day) despite countless attempts; the patient can repeat each fact as it is presented, indicating that he understands what is wanted of him and that “registration” is intact; but by the time the third fact is repeated, the first may have been forgotten. However, certain subtle learning may take place; for example, with repeated trials, the patient may learn complex tasks such as mirror writing or how to negotiate a maze, despite no recollection of ever having been confronted with these tasks.

Anterograde amnesia is always coupled with a disturbance of past or remote memory (retrograde amnesia). The latter disorder is usually severe in degree, though rarely complete, and covers a period that antedates the onset of the illness by several years. Characteristically, a few isolated events and information from the past are retained, but these are related without regard for the intervals that separated them or for their proper temporal sequence. Usually the patient “telescopes” events; sometimes the opposite occurs. This aspect of the memory disorder becomes prominent as the initial (global confusional) stage of the illness subsides and some improvement in memory function occurs; this may account for certain instances of confabulation (see below).

It is probably true that memories of the recent past are more severely impaired than those of the remote past (Ribot’s rule); language, computation, knowledge acquired in school, and all habitual actions are preserved. This is not to say that all remote memories are intact. These are not as readily tested as more recent memories; the two are therefore difficult to compare. It is our impression that there are gaps and inaccuracies in memories of the distant past in practically all cases of the Korsakoff amnesic state and serious impairments in many.

It should be emphasized that the cognitive impairment of the Korsakoff patient cannot be explained in terms of memory loss alone, even though this is the most critical functional loss. Psychologic testing discloses that certain cognitive and perceptual functions that depend little or not at all on retentive memory are also impaired. The most consistent failure is with the digit symbol task and, to a lesser degree, with arithmetic and block design. Also as a rule, the Korsakoff patient has no insight into his illness and is characteristically apathetic and inert, lacking in spontaneity and initiative and indifferent to everything and everybody around him. However, the patient has a relatively normal capacity to reason with data immediately before him.

**Confabulation** has generally been considered to be a specific feature of Korsakoff psychosis. The validity of this view depends...
largely on how one defines confabulation, and there is no uniformity of opinion on this point. The observations of our colleague M. Victor do not support the oft-repeated statement that the Korsakoff patient fills the gaps in his memory with confabulation. In the sense that gaps in memory exist and that whatever the patient supplies in place of the correct answers fills these gaps, the statement is incontrovertible. It is hardly explanatory, however. The implication that confabulation is a deliberate attempt to hide the memory defect, out of embarrassment or for other reasons, is probably not correct. In fact, the opposite seems to pertain: as the patient improves and becomes more aware of a defect in memory, the tendency to confabulate diminishes.

In our experience, confabulation can be associated with both phases of the Wernicke-Korsakoff syndrome: the initial phase, in which profound general confusion dominates the disease; and the convalescent phase, in which the patient recalls fragments of past experience in a distorted fashion. Events that were separated by long intervals are juxtaposed or related out of sequence, so that the narrative has an implausible or fictional aspect. Whether one designates the latter defect as confabulation or as a particular defect of retentive memory is academic. In the chronic, stable state of the disease, confabulation is usually absent. These and other aspects of confabulation are discussed more fully in the monograph by Victor and colleagues.

Other Clinical Abnormalities Signs of peripheral neuropathy are found in more than 80 percent of patients with the Wernicke-Korsakoff syndrome. In most the neuropathic disease is mild and does not account for the disorder of gait, but it may be so severe that stance and gait cannot be tested. In a small number, retrobulbar optic neuropathy is added. Despite the frequency of peripheral neuropathy, overt signs of beriberi heart disease are rare. However, indications of disordered cardiovascular function—such as tachycardia, exertional dyspnea, postural hypotension, and minor electrocardiographic abnormalities—are frequent; occasionally, the patient dies suddenly, following only slight exertion. These patients may show an elevation of cardiac output associated with low peripheral vascular resistance—abnormalities that revert to normal after the administration of thiamine. Postural hypotension and syncope are common findings in Wernicke disease and are probably due to impaired function of the autonomic nervous system, more specifically to a defect in the sympathetic outflow (Birchfield). There may be mild hypothermia, loss of libido, and impotence. Patients with the Korsakoff amnesic state may have a demonstrably impaired olfactory discrimination. This deficit, like the notable aphathy present in most Wernicke patients, is probably attributable to a lesion of the mediodorsal nucleus of the thalamus and its connections and not to a lesion of the peripheral olfactory system (Mair et al).

Ancillary Laboratory Findings The acute lesions of the Wernicke-Korsakoff syndrome, both the medial thalamic and periaqueductal ones, can be demonstrated by magnetic resonance imaging (MRI) (Donnell et al; Varnet et al). The changes are most apparent on the FLAIR and T2-weighted images but also on diffusion-weighted sequences; the latter is worthy of emphasis because changes of Wernicke disease may be mistaken for infarction on these images. Imaging is particularly useful in patients in whom stupor or coma has supervened or in whom ocular and ataxic signs are otherwise inconstant (Victor, 1990). With clinical improvement, the imaging changes are reversible.

The cerebrospinal fluid (CSF) in uncomplicated cases of the Wernicke-Korsakoff syndrome is normal or shows only a modest elevation of the protein content. Protein values above 100 mg/dL or a pleocytosis should suggest the presence of a complicating illness—subdural hematoma, meningeval infection, and herpes encephalitis being the most common.

Vestibular function, as measured by the response to standard ice-water calorics, is universally impaired in the acute stage of Wernicke disease (Ghez). Vertigo is not a complaint, however. To this abnormality of function, which is more or less symmetrical, the term vestibular paresis has been applied. It probably accounts for the severe disequilibrium in the initial stage of the illness.

Blood pyruvate is elevated in untreated Wernicke disease, but blood transketolase activity is a more accurate index of the thiamine deficiency. Transketolase, one of the enzymes of the hexose monophosphate shunt, requires thiamine pyrophosphate (TPP) as a copfactor. In normal adult subjects, transketolase values (expressed as sedoheptulose-7-phosphate produced per milliliter per hour) range from 90 to 140 mg and the TPP effect from 0 to 10 percent, depending on the degree of vitamin supplementation. Before specific treatment with thiamine, patients with Wernicke disease show a marked reduction in their transketolase activity (as low as one-third of normal values) and a striking TPP effect (up to 50 percent). Restoration of these values toward normal occurs within a few hours of the administration of thiamine, and completely normal values are usually attained within 24 h.

An additional abnormality of transketolase has been described by Blass and Gibson. They found that transketolase in cultured fibroblasts from four alcoholics with Wernicke-Korsakoff disease bound TPP less avidly than did the transketolase from control lines. Presumably this defect would be insignificant if the diet were adequate but would be deleterious if the diet were low in thiamine. These findings, which have been corroborated by Mukherjee and colleagues, suggest a hereditary factor in the genesis of Wernicke-Korsakoff disease and possibly may explain why only a small proportion of nutritionally deficient alcoholics develop this disease.

Only about half the patients with Wernicke-Korsakoff disease show electroencephalographic (EEG) abnormalities, consisting of diffuse mild to moderate slow activity. Total cerebral blood flow and cerebral oxygen and glucose consumption may be greatly reduced in the acute stages of the disease, and these defects may still be present after several weeks of treatment (Shimojiyo et al). These observations indicate that significant reductions in brain metabolism need not be reflected in EEG abnormalities or in depression of the state of consciousness and that the latter is more a function of the location of the lesion than of the overall degree of metabolic defect.

Course of the Illness The mortality rate in the acute phase of Wernicke disease was 17 percent in the series of patients collected by Victor and Adams. The fatalities were attributable mainly to hepatic failure and to infection (pneumonia, pulmonary tuberculosis, and septicemia being the most common). Some deaths were undoubtedly due to the effects of thiamine deficiency that had reached an irreversible stage.

Most patients respond in a fairly predictable manner to the administration of thiamine, as detailed further on. The most dramatic improvement is in the ocular manifestations, as already mentioned. Recovery begins often within hours after the administration of thiamine and practically always within several days. This effect is so constant that a failure of the ocular palsies to respond to thiamine should raise doubts about the diagnosis of Wernicke disease. Sixth nerve palsies, ptosis, and vertical gaze palsies recover completely within a week or two in most cases, but vertical nys-
tagnus may sometimes persist for several months. Horizontal gaze palsies recover completely as a rule, but in 60 percent of cases a fine horizontal nystagmus remains as a permanent sequela. In this respect, horizontal nystagmus is unique among the ocular signs.

In comparison with the ocular signs, improvement of ataxia is somewhat delayed. About 40 percent of patients recover completely from ataxia. The remainder recover incompletely or not at all and are left with a slow, shuffling, wide-based gait and inability to walk tandem. The residual gait disturbances and horizontal nystagmus provide a means of identifying obscure and chronic cases of dementia as alcoholic-nutritional in origin. Vestibular function improves at about the same rate as the ataxia of gait, and recovery is usually but not always complete.

The early symptoms of apathy, drowsiness, and global confusion invariably recede, and as they do the defect in memory and learning stands out more clearly. However, the memory disorder, once established, recovers completely or almost completely in only 20 percent of patients. The remainder are left with varying degrees of permanent disability.

It is apparent from the foregoing account that Wernicke disease and Korsakoff psychosis are not separate diseases but that the changing ocular and ataxic signs and the transformation of the global confusional state into an amnestic syndrome are simply successive stages in a single disease process. Of 186 patients in the series of Victor and Adams who presented with Wernicke disease and survived the acute illness, 157 (84 percent) showed this sequence of clinical events. As a corollary, a survey of alcoholic patients with Korsakoff psychosis in a state mental hospital disclosed that in most the illness had begun with the symptoms of Wernicke disease and that about 60 percent of them still showed the ocular cerebellar stigmata of Wernicke disease many years after the onset. The same type of continuum cannot be invoked to explain alcoholic-nutritional cerebellar degeneration that most often arises as an independent illness and not as a residual of the ataxia of Wernicke disease.

Neuropathologic Findings and Clinicopathologic Correlation

Patients who die in the acute stages of Wernicke disease show symmetrical lesions in the paraventricular regions of the thalamus and hypothalamus, mammillary bodies, periaqueductal region of the midbrain, floor of the fourth ventricle (particularly in the regions of the dorsal motor nuclei of the vagus and vestibular nuclei), and superior cerebellar vermis. Lesions are consistently found in the mammillary bodies and less consistently in the other areas. The microscopic changes are characterized by varying degrees of necrosis of parenchymal structures. Within the area of necrosis, nerve cells are lost, but usually some remain; some of these are damaged but others are intact. Myelinated fibers are more affected than neurons. These changes are accompanied by a prominence of the blood vessels, although in some cases there appears to be a primary endothelial proliferation and evidence of recent or old petechial hemorrhage. In the areas of parenchymal damage there is astrocytic and microglial proliferation. Discrete hemorrhages were found in only 20 percent of our cases, and many appeared to be agonal in nature. The cerebellar changes consist of a degeneration of all layers of the cortex, particularly of the Purkinje cells; usually this lesion is confined to the superior parts of the vermis, but in advanced cases the cortex of the most anterior parts of the anterior lobes is involved as well. Of interest is the fact that the lesions of Leigh’s encephalomyelopathy—a mitochondrial disorder implicating pyruvate metabolism—have been found (page 843); these bear a close resemblance to those of Wernicke disease but have a slightly different distribution and histologic characteristics.

The ocular muscle and gaze palsies are attributable to lesions of the sixth and third nerve nuclei and adjacent tegmentum and the nystagmus to lesions in the regions of the vestibular nuclei. The latter are also responsible for the loss of caloric responses and probably for the gross disturbance of equilibrium that characterizes the initial stage of the disease. The lack of significant destruction of nerve cells in these lesions accounts for the rapid improvement and the high degree of recovery of oculomotor and vestibular functions. The persistent ataxia of stance and gait is due to the lesion of the superior vermis of the cerebellum; ataxia of individual movements of the legs is attributable to an extension of the lesion into the anterior parts of the anterior lobes. Hypothermia, which occurs sometimes as a presenting feature of Wernicke disease, is probably attributable to lesions in the posterior and posterolateral nuclei of the hypothalamus (experimentally placed lesions in these parts have been shown to cause hypothermia or poikilothermia in monkeys).

The topography of the neuropathologic changes in patients who die in the chronic stages of the disease, when the amnestic symptoms predominate, is much the same as the changes in the acute stages of Wernicke disease. Apart from the expected differences in age of the glial and vascular reactions, the only important difference has to do with the involvement or lack of involvement of the medial dorsal and anterior nuclei of the thalamus. The medial parts of these nuclei were consistently involved in the patients who had shown the Korsakoff amnesic state during life; they were not affected in patients who had had no persistent amnestic symptoms in the series of Victor and Adams. The mammillary bodies were affected in all of the patients, both those with the amnestic defect and those without. These observations suggest that the lesions responsible for the memory disorder are those of the thalami, predominantly of parts of the medial dorsal nuclei (and their connections with the medial frontal and temporal lobes and amygdaloid nuclei, i.e., a thalamic amnestic state), and not those of the mammillary bodies, as is frequently stated. It is also notable that the hippocampal formations, the site of damage in most other types of Korsakoff memory loss, are intact.

Treatment of the Wernicke-Korsakoff Syndrome

Wernicke disease constitutes a medical emergency; its recognition (or even the suspicion of its presence) demands the immediate administration of thiamine. The prompt use of thiamine prevents progression of the disease and reverses those lesions that have not yet progressed to the point of fixed structural change. As emphasized earlier, in patients who show only ocular signs and ataxia, the administration of thiamine is crucial in preventing the development of an irreversible amnestic state.

Although 2 to 3 mg of thiamine may be sufficient to modify the ocular signs, much larger doses are needed to sustain improvement and replenish the depleted thiamine stores—50 mg intravenously and 50 mg intramuscularly—the latter dose being repeated each day until the patient resumes a normal diet.

In order to avoid precipitating Wernicke disease, it has also become standard practice in emergency departments to administer 50 to 100 mg of thiamine simultaneously if intravenous fluids that contain glucose are being infused. It is also advisable to give B vitamins to alcoholic patients who are seen for other reasons in the emergency department. The chronic alcoholic (or the nonalcoholic with persistent vomiting) exhausts his body stores of thiamine.
in a matter of 7 or 8 weeks, during which time the administration of glucose may serve to precipitate Wernicke disease or cause an early form of the disease to progress rapidly. The further management of Wernicke disease involves the use of a balanced diet and all the B vitamins, since the patient is usually deficient in more than thiamine alone.

A problem in management may arise once the patient has recovered from Wernicke disease and the amnesic syndrome becomes prominent. As indicated above, only a minority of such patients (less than 20 percent in our series) recover; moreover, the time of recovery may be delayed for several weeks or even months, and then it proceeds very slowly over a period of many months. The extent to which the amnesic symptoms will recover cannot be predicted accurately during the acute stages of the illness; one must guard against the premature commitment of the patient to a mental hospital. Interestingly, the alcoholic Korsakoff patient, once more or less recovered, seldom demands alcohol but will drink it if it is offered.

Infantile Wernicke-Beriberi Disease This term designates an acute and frequently fatal disease of infants, which until recently was common in rice-eating communities of the Far East. It affects only breast-fed infants, usually in the second to the fifth months of life. Acute cardiac symptoms dominate the clinical picture, but neurolologic symptoms (aphonia, strabismus, nystagmus, spasmodic contraction of facial muscles, and convulsions) have been described in many of the cases. This syndrome can be reversed dramatically by the administration of thiamine, so that some authors prefer to call it acute thiamine deficiency in infants. In the few neuropathologic studies that have been made, changes like those of Wernicke disease in the adult have been described.

Infantile beriberi bears no consistent relationship to beriberi in the mother. Infants of mothers with overt signs of beriberi may be quite normal. Conversely, mothers of infants with beriberi may themselves be free of the disease. The absence of beriberi in the mothers of affected infants suggests that infantile beriberi might be due to a toxic factor in breast milk, but such a factor, if it exists, has never been isolated. The levels of thiamine in the breast milk of such mothers have not been measured, however.

Rarely, the clinical manifestations of beriberi in infancy represent an inherited (autosomal recessive) thiamine-dependent state, corresponding to the continued administration of massive doses of thiamine (Mandel et al; see also Table 43-1, further on).

**NUTRITIONAL POLYNEUROPATHY (NEUROPATHIC BERIBERI)**

Most physicians in the western world have only a dim notion about beriberi, which they recall as an ill-defined, predominantly cardiac disorder occurring among the rice-eating people of the Orient. In fact, beriberi is a distinct clinical entity that is not confined to any particular part of the world. Essentially it is a disease of the heart and of the peripheral nerves (which may be affected separately), with or without edema, the latter feature providing the basis for the classic division into “wet” and “dry” forms. The cardiac manifestations range from tachycardia and exertional dyspnea to acute and rapidly fatal heart failure. This is the most dramatic manifestation of beriberi, but it is uncommon. Here we are concerned with the affection of the peripheral nerves, or neuropathic beriberi, as it is called.

That beriberi is essentially a degenerative disorder of the peripheral nerves was established in the late nineteenth century by the classic studies of the Dutch investigators Eijkman, Pekelharing and Winkler, and Grijns. Only after beriberi gained acceptance as a nutritional disease (this followed Funk’s discovery of vitamins in 1911) was it suspected that the neuropathy of alcoholics was also nutritional in origin. The similarity between beriberi and alcoholic neuropathy was commented upon by several authors, but it was Shattuck, in 1928, who first seriously discussed the relationship of the two disorders. He suggested that “polyneuritis of chronic alcoholism was caused chiefly by failure to take or assimilate food containing a sufficient quantity of vitamin B . . . and might properly be regarded as true beriberi.” Convincing evidence that “alcoholic neuritis” is not due to the neurotoxic effect of alcohol was supplied by Strauss. He allowed 10 patients to continue their daily consumption of whiskey while they consumed a well-balanced diet supplemented with yeast and vitamin B concentrates; the peripheral nerve symptoms improved in every case. Our own observations support Strauss’s contention that alcoholic polyneuropathy is essentially a nutritional disease.

**Clinical Features** The symptomatology of nutritional polyneuropathy is diverse. In fact, many patients are asymptomatic, and evidence of peripheral nerve affection is found only on clinical or electromyographic examination. In the latter circumstance the neuropathic signs are mild in degree, consisting of thinness and tenderness of the leg muscles, loss or depression of the Achilles reflexes and paternal reflexes, and at times a patchy blunting of pain and touch sensation over the feet and shins.

The majority of patients, however, are symptomatic—weakness, paresthesias, and pain being the usual complaints. The symptoms are insidious in onset and slowly progressive, but occasionally they seem to evolve or to worsen rapidly over a matter of days. The initial symptoms are usually referred to the distal portions of the limbs and progress proximally if the illness remains untreated. The feet are always affected earlier and more severely than the hands. Most often some aspect of motor disability constitutes the chief complaint, but in about one-quarter of the patients the main complaints are pain and paresthesias. The painful syndrome has been prominent in the patients we have encountered in recent years. The discomfort takes several forms: a dull, constant ache in the feet or legs; sharp and lancinating pains, momentary in duration, like those of tabes dorsalis; sensations of cramping or tightness in the muscles of the feet and calves; or band-like feelings around the legs. Coldness of the feet is a common complaint but is purely subjective. Far more distressing are feelings of heat or “burning” affecting mainly the soles, less frequently the dorsal aspects of the feet. The dysesthesias fluctuate in severity and characteristically are worsened by contactual stimuli, sometimes to the point where the patient cannot walk or bear the touch of bedclothes, despite the relative preservation of motor power. The term burning feet has been applied to this syndrome, but it is not particularly apt, since the patient also complains of other types of paresthesias and pain, and these symptoms may involve the hands as well as the feet.

Examination discloses varying degrees of motor, sensory, and reflex loss. As the symptoms suggest, the signs are symmetrical, usually more severe in distal than in proximal portions of the limbs, and often confined to the legs. The disproportionate affection of motor power may be striking, taking the form of a foot and wrist drop; but even in these patients the proximal muscles are usually affected as well (indicated by difficulty in arising from a squatting
position). In other patients, all the leg muscles are affected more or less equally, and in a few, weakness appears to be most severe in the proximal muscles. Absolute paralysis of the legs is observed only rarely; immobility due to contractures at the knees and ankles is a more common occurrence. Tenderness of muscles on deep pressure is a highly characteristic finding, elicited most readily in the muscles of the feet and calves. Deep tendon reflexes in the legs are almost always lost, even when weakness is slight in degree. In the arms, tendon reflexes are sometimes retained despite a loss of strength in the hands. In those in whom pain and dysesthesias are prominent and motor loss is slight, the reflexes at knee and ankle may be retained or even of greater than average briskness.

Excessive sweating of the soles and dorsal aspects of the feet and of the volar surfaces of the hands and fingers is a common manifestation of alcohol-induced nutritional neuropathy. Postural hypotension is sometimes associated. These symptoms are indicative of involvement of the peripheral sympathetic nerve fibers.

Sensory loss or impairment may involve all the modalities, although one may be affected out of proportion to the others. One cannot predict from the patient’s symptoms which mode of sensation might be affected disproportionately. In patients with impairment of superficial sensation (i.e., touch, pain, and temperature), the border between impaired and normal sensation is not sharp but shades off gradually over a considerable vertical extent of the limbs.

Patients in whom pain is the outstanding symptom do not constitute a distinct group in terms of their neurologic signs. Pain and dysesthesias may be prominent in patients with either severe or slight degrees of motor, reflex, and sensory loss. The term hyperesthetic is used commonly to designate the exquisitely painful form of neuropathy but is not well chosen; as pointed out on page 118, one is usually able, by using finely graded stimuli, to demonstrate an elevated threshold to painful, thermal, and tactile stimuli in the “hyperesthetic” zone. Once the stimulus is perceived, however, it has a painful and diffuse, unpleasant quality (hyperpathia). Tactile evocation of pain or burning is an example of allodynia.

In most patients with nutritional polyneuropathy, only the limbs are involved and the abdominal, thoracic, and bulbar muscles are usually spared; however, we have encountered two cases in which there was sensory loss in the pattern of an escutcheon over the anterior thorax and abdomen. In the most advanced instances of neuropathy, hoarseness and weakness of the voice and dysphagia due to affection of the vagus nerves may be added to the clinical picture.

Some idea of the incidence of the motor, reflex, and sensory abnormalities and the combinations in which they occur can be obtained from Table 41-1, which is based on Victor’s examination of 189 nutritionally depleted alcoholic patients. Noteworthy is the fact that only 66 (35 percent) of the 189 patients showed the clinical picture of polyneuropathy in its entirety—i.e., a symmetrical impairment or loss of tendon reflexes, sensation, and motor power affecting legs more than the arms and the distal more than the proximal segments of the limbs. In the remaining patients, the motor-reflex-sensory signs occurred in various combinations, as indicated in Table 41-1.

forefeet”), have been described but are rare. Repeated trauma to insensitive parts and superimposed infection are thought to be responsible for the neuropathic arthropathy.

The CSF is usually normal, although a modest elevation of protein content is found in a small number of cases. Electromyographic (EMG) findings include mild to moderate degrees of slowing of motor and sensory conduction and a marked reduction of the amplitudes of sensory action potentials; the motor conduction velocities in distal segments of the nerves may be reduced, while conduction in proximal segments is normal. Denervated muscles show fibrillation potentials.

Pathologic Features The essential pathologic change is one of axonal degeneration, with destruction of both axon and myelin sheath. Segmental demyelination may also occur, but only in a small proportion of fibers. This change may be difficult to discern in myelin-stained sections of whole nerve trunks, but it can be observed in teased nerve fibers stained with osmium. The most pronounced changes are observed in the distal parts of the longest and largest myelinated fibers in the crural and, to a lesser extent, brachial nerves. In advanced cases the degenerative changes extend into the anterior and posterior nerve roots. The vagus and phrenic nerves and paravertebral sympathetic trunks may be affected in advanced cases.

Anterior horn and dorsal root ganglion cells undergo chromatolysis, indicating axonal damage. Degenerative changes in the posterior columns are seen in some cases and are probably secondary to the changes in the dorsal spinal roots.

Pathophysiology The nutritional factor(s) responsible for the neuropathy of alcoholism and beriberi have not been defined precisely. Because of the difficulties in producing peripheral neuropathy in mammals by means of a thiamine-deficient diet, several investigators in the past questioned the idea that thiamine is the antineuritic vitamin. Very few of the animal experiments undertaken to settle this point are satisfactory from a nutritional and pathologic point of view. Nevertheless, several studies in birds and humans do indicate that uncomplicated thiamine deficiency may result in peripheral nerve disease. The necessity of either accepting or rejecting the specific role of thiamine became less urgent when it was demonstrated, in both animals and humans, that a deficiency of pyridoxine or of pantothentic acid could also result in degeneration of the peripheral nerves (see Swank and Adams).

The question of whether polyneuropathy in the alcoholic patient might be due to the direct toxic effects of alcohol and not to...
a nutritional deficiency has again been raised from time to time (see, for example, Denny-Brown and Behse and Buchthal). The evidence for this view is not compelling, either on clinical or on experimental grounds, as already mentioned (see reference to Strauss, in introductory section on nutritional neuropathy). The data presented recently by Koike and colleagues, ostensibly in favor of the existence of a true alcoholic neuropathy, suggest that thiamine is not the proximate cause, but in our view they present no convincing support of a direct toxic effect of alcohol. The interested reader will find a detailed critique of this subject in the chapters by Victor and by Windebank in the second and third editions, respectively, of *Peripheral Neuropathy*, edited by Dyck and coworkers.

**Treatment and Prognosis**  The first consideration is to supply adequate nutrition in the form of a balanced diet supplemented with B vitamins. Equally important is to make certain that the patient follows the prescribed diet. If persistent vomiting or other gastrointestinal complications prevent the patient from eating, then parenteral feeding becomes necessary; the vitamins may be given intramuscularly or added to intravenous fluids.

Where pain and sensitivity of the feet are the major complaints, the pressure of bedclothes may be avoided by placing a cradle support over the legs. Aching of the limbs may be related to their immobility, in which case they should be moved passively on frequent occasions. Aspirin or acetylsalicylic acid is usually sufficient to control hyperpathia; occasionally codeine in doses of 15 to 30 mg may be used. Obviously, opiates and addicting synthetic analgesics should be avoided. Some of our patients with severe burning pain (similar to causalgia) in the feet had in the past been helped temporarily by blocking the lumbar sympathetic ganglia or by epidural injection of analgesics. The response to phenytoin, carbamazepine, and gabapentin has been inconsistent in our experience. Adrenergic blocking medication has been of little value and mexiletine, of uncertain benefit.

The regeneration of peripheral nerves, which may take many months, will be of no avail if the muscles have been allowed to undergo contracture and the joints to become fixed. In cases of severe paralysis, molded splints should be applied to the arms, hands, legs, and feet during periods of rest. Pressure on the heels and elbows can be avoided by padding the splints and by turning the patient frequently or by asking the patient to do so. As soon as the patient’s general condition permits, the limbs must be passively moved through a full range of movement several times daily. As function returns, more vigorous physiotherapeutic measures can be undertaken.

Recovery from nutritional polyneuropathy is a slow process. In the mildest cases there may be a considerable restoration of motor function in a few weeks. In severe forms of the disease, several months may pass before the patient is able to walk unaided. The sensory features and pain in particular may be slower to recover, having taken a year on one of our recently observed patients. The slowness of recovery creates a special problem for the alcoholic patient, in whom the great danger to continued recovery is the resumption of drinking and inadequate diet. Suitable arrangements must therefore be made for close supervision during the long and tedious convalescence.

**Pellagra**

In the early 1900s, pellagra attained epidemic proportions in the southern United States and in the alcoholic population of large urban centers. Since 1940, it has diminished greatly because of the general practice of enriching bread with niacin. Nevertheless, among the vegetarian, maize-eating people of underdeveloped countries and among the black population of South Africa, pellagra is still a common disease (Bomb et al, Shah et al, Ronthal and Adler). In developed countries, pellagra is practically confined to alcoholics (Ishii and Nishihara, Spivak and Jackson, Serdar et al).

**Clinical Features in Typical Cases**  In its fully developed form, pellagra affects the skin, alimentary tract, and hematopoietic and nervous systems. The early symptoms may be mistaken for those of a psychosis. Insomnia, fatigue, nervousness, irritability, and feelings of depression are common complaints; examination may disclose mental dullness, apathy, and an impairment of memory. Sometimes an acute confusional psychosis dominates the clinical picture. Untreated, these symptoms may progress to a dementia. Pellagra may not only produce insanity but occasionally result from it, by virtue of the anorexia and refusal of food that accompany certain mental illnesses. The dermatologic feature, often permitting one to make a confident diagnosis, is a *scaly dermatitis in sun-exposed areas*. Diarrhea and glossitis or other forms of mucous membrane disorder may be accompaniments. (Hence the alliterative triad dementia-dermatitis-diarrhea.) The *spinal cord* manifestations have not been clearly described; in general, the signs are referable to both the posterior and lateral columns, predominantly the former. Signs of *peripheral nerve affection* are relatively less common and are indistinguishable from those of neuropathic beriberi.

**Pathologic Changes**  These are most readily discerned in the large cells of the motor cortex, the cells of Betz, and are seen to a lesser extent in the smaller pyramidal cells of the cortex, the large cells of the basal ganglia, the cells of the cranial motor and dentate nuclei, and the anterior horn cells of the spinal cord. The affected cells appear swollen and rounded, with eccentric nuclei and loss of the Nissl bodies (frequently referred to as “axonal reaction”). In the pathologic material of Hauw and associates, the chromatolytic changes were most pronounced in the brainstem nuclei (upper reticular and pontine) and not in the Betz cells. They concluded that these changes were not due to a retrograde axonal lesion but did not comment on the status of the spinal cord.

The spinal cord lesions in pellagra take the form of a symmetrical degeneration of the dorsal columns, especially of Goll, and to a lesser extent of the corticospinal tracts. Such a posterior column degeneration, affecting a specific system of fibers, is likely to be secondary to degeneration of the dorsal root ganglion cells or posterior roots. The reason for the corticospinal tract degeneration is not clear. The few studies of the peripheral nerves in pellagra have disclosed changes like those in alcoholics and other patients with nutritional deficiency.

**Etiology**  It has been known since 1937—when Elvehjem and coworkers showed that nicotinic acid cured black tongue, a pellagra-like disease in dogs—that this vitamin is effective in the treatment of pellagra. Many years before, Goldberger had demonstrated the curative effects of dietary protein and proposed that pellagra was caused by a lack of specific amino acids (see Terris). Now it is known that pellagra may result from a deficiency of either nicotinic acid or tryptophan, the amino acid precursor of nicotinic acid. One milligram of nicotinic acid is formed from 60 mg of tryptophan, a process for which pyridoxine is essential. (Because niacin can be biosynthesized from tryptophan, this is not strictly speaking a vitamin deficiency disorder.) The relationship of niacin to tryptophan metabolism explains the frequent occurrence of pel-
lagra in persons who subsist mainly on corn, which contains only small amounts of tryptophan and niacin—some of the niacin being in bound form and unavailable for absorption.

It should be pointed out that, in experimental subjects, only the cutaneous-gastrointestinal-neurasthenic manifestations of pellagra have been produced by the feeding of tryptophan- or niacin-deficient diets; neurologic abnormalities were not produced by these diets (Goldsmith). As a corollary, only the dermal, gastrointestinal, and neurasthenic manifestations respond to treatment with niacin and tryptophan; neurologic disturbances in pellagrins have proved to be recalcitrant to prolonged treatment with nicotinic acid, although the peripheral nerve disorder may subsequently respond to treatment with thiamine. In monkeys, degeneration of peripheral nerves as well as the unique cerebrocortical changes of pellagra were induced by a deficiency of pyridoxine (Victor and Adams, 1956). Swank and Adams described degeneration of the peripheral nerves in pyridoxine- and pantothenic acid–deficient swine, and Vilter and colleagues produced polynuropathy in human subjects rendered pyridoxine-deficient; these subjects also showed seborrhic dermatitis and glossitis (indistinguishable from that of niacin deficiency) and the cheilosis and angular stomatitis that are usually attributed to riboflavin deficiency. The foregoing observations indicate that certain lingual and cutaneous manifestations of pellagra may be produced by a deficiency of pyridoxine or other B vitamins and that the neurologic manifestations of pellagra are most likely due to pyridoxine deficiency.

In the special case of Hartnup disease (which resembles pellagra in most respects including the dermatitis), a niacin deficiency is believed to result from the high excretion of indicans and indole metabolites (see page 818).

**Nutritional Spinal Spastic and Ataxic Syndrome** This syndrome is observed occasionally in nutritionally depleted alcoholics. The main clinical signs are spastic weakness of the legs, with absent abdominal and increased tendon reflexes, clonus, extensor plantar responses, and a loss of position and vibratory senses. In our experience, this syndrome is usually associated with other nutritional disorders, such as Wernicke disease and peripheral and optic neuropathy. In prisoner-of-war camps, the “spastic syndrome” was observed in association with mental and emotional changes and diminishment of vision, and at times with widespread muscular rigidity, confusion, coma, and death. The latter syndrome has never been studied pathologically, so that it is impossible to state whether the lesions are the same as or different from those of pellagra or from Strachan syndrome, described further on.

The syndromes of tropical spastic paraparesis and of lathyrism, another form of spastic paraplegia common in India and certain parts of Africa, were, for many years suspected of being nutritional in origin but are now known to be due to a virus and a toxin, respectively. These and other types of tropical spastic paraplegia are discussed in greater detail with the spinal cord diseases (Chap. 44). A chronic tropical disease of the peripheral nerves, called “ataxic neuropathy of Nigeria,” has been attributed to the ingestion of inadequately detoxified cassava (Osuntokun). Another form of spastic ataxia called “konzo” has been attributed to the production of cyanide by an ingested toxic glycoside in individuals who are protein deficient. The differential diagnosis of spastic ataxia is quite broad and includes especially multiple sclerosis.

**Nicotinic Acid Deficiency Encephalopathy** Under this title, Jolliffe and coworkers, in 1940, described an acute cerebral syndrome in alcoholic patients consisting of clouding of consciousness, progressing to extrapyramidal rigidity and tremors (“cogwheel” rigidity) of the extremities, uncontrollable grasping and sucking reflexes, and coma. Some of their patients showed overt manifestations of nutritional deficiency, such as Wernicke disease, pellagra, scurvy, and polyneuropathy. These authors concluded that the encephalopathy represented an acute form of nicotinic acid deficiency, since most of their patients recovered when treated with a diet of low vitamin B content supplemented by intravenous glucose and saline and large doses of nicotinic acid. Sydenstricker and colleagues (1938) had previously reported the salutary effects of nicotinic acid on the unresponsive state observed in elderly undernourished patients, and Spillane (1947) described a similar syndrome and response to nicotinic acid in the indigent Arab population of the Middle East.

The status of this syndrome and its relation to pellagra are uncertain. The clinical, nutritional, and pathologic features were not delineated precisely. Serdaru and associates reported 22 presumed examples of this syndrome in the alcoholic population of the Salpétrière clinic in Paris, all diagnosed retrospectively after the finding in postmortem material of pellagra-like changes in nerve cells. Prominent were confusional states, oppositional, paralytic rigidity (gegenhalten), ataxia, and polymyoclonia—a picture somewhat like that described by Jolliffe and coworkers (above). Skin lesions were absent. We have not encountered identical cases among the undernourished patients in the alcoholic populations of Boston and Cleveland.

**Deficiency Amblyopia (Nutritional Optic Neuropathy) “Tobacco-Alcohol Amblyopia”** (See also Chap. 13)

These terms refer to a characteristic form of visual impairment that results from nutritional deficiency. The defect in vision is due to a lesion of the optic nerves, more or less confined to the region of the papillomacular bundle.

Typically, the patient complains of dimness or blurring of vision for near and distant objects, evolving gradually over a period of several days or weeks. Examination discloses a reduction in visual acuity due to the presence of central or centrocecal scotomata, which are larger for colored than for white test objects. Pallor of the temporal portion of the optic disc is observed in some cases. These abnormalities are bilateral and roughly symmetrical and, if untreated, may progress to blindness and irreversible optic atrophy. With nutritious diet and vitamin supplements, improvement occurs in all but the most chronic cases, the degree of recovery depending upon the severity of the amblyopia and particularly upon its duration before therapy is instituted.

Although the precise deficiency responsible for this disease cannot be named, its nutritional basis was established beyond doubt during World War II and the Korean War, when innumerable instances were observed in prisoners of war who had been confined for prolonged periods under conditions of severe dietary deprivation. Fisher described the optic nerve lesions in four such patients who had died of unrelated causes between 8 and 10 years after the onset of amblyopia. In each case there was a loss of myelin and axis cylinders restricted to the region of the papillomacular fibers. Of the four cases, three also showed demyelination of the posterior columns of the spinal cord, no doubt an expression of the associated sensory polyradiculopathy.

In the western world, a visual disorder indistinguishable clinically and pathologically from that observed in prisoners of war is observed infrequently, mainly among undernourished alcoholics.
For many years this has been referred to as tobacco-alcohol amblyopia, with the implication that the visual loss is due to the toxic effects of alcohol, tobacco, or both. Actually, the evidence is overwhelming that so-called tobacco-alcohol amblyopia is due to nutritional deficiency and not to toxic exposure. A specific nutrient has not been identified, however. There are data in humans and in animals that under certain conditions a deficiency of one or more of the B vitamins—thiamine, vitamin B₁₂, and perhaps riboflavin—may cause degenerative changes in the optic nerves, a situation that pertains in the peripheral nerves as well.

In the 1960s, a popular theory held that the combined effects of vitamin B₁₂ deficiency and chronic poisoning by cyanide (generated in tobacco smoke) were responsible for “tobacco amblyopia.” Vitamin B₁₂ deficiency is a rare but undoubted cause of optic neuropathy (page 994), but the notion that cyanide or other substances in tobacco smoke have a damaging effect on the optic nerves is supported neither by logic nor by experimental data (see reviews of Potts and of Victor). Clinically, instances of Leber hereditary optic atrophy, a mitochondrial disorder, may be mistaken for “tobacco-alcohol amblyopia”—an error that should be made less often because the former disorder can now be identified by mitochondrial DNA testing.

Recent outbreaks of an apparently nutritional or perhaps toxic optic neuropathy occurred in Cuba during 1991–1993 and in Tanzania. In both instances the optic neuropathy was frequently associated with peripheral neuropathy; therefore these conditions are considered below, with the Strachan syndrome.

**Syndrome of Amblyopia, Painful Neuropathy, and Orogenital Dermatitis (“Strachan Syndrome”)**

There remains to be considered a neurologic syndrome that almost certainly is nutritional in origin but does not conform clinically to beriberi or Pellagra, the classic deficiency diseases. This syndrome was originally observed by Strachan in 1897 among Jamaican sugar cane workers. The main symptoms in his patients were pain, numbness, and paresthesias of the extremities; objectively there was ataxia of gait, weakness, wasting, and loss of deep tendon reflexes and sensation in the limbs. Dimness of vision and impairment of hearing were common findings, as were soreness and excoriation of the mucocutaneous junctions of the mouth. This disorder, originally known as “Jamaican neuritis,” was quickly recognized in other parts of the world, particularly in the undernourished populations of tropical countries. Subsequently, many cases of this syndrome were observed in the besieged population of Madrid during the Spanish Civil War and during World War II among prisoners of war in North Africa and the Far East.

As indicated earlier, a massive outbreak of a similar disorder, affecting more than 50,000 persons, occurred in Cuba from late 1991 through 1993. The association of this epidemic with widespread dietary deprivation and the salutary response of both optic and peripheral nerve symptoms to treatment with B vitamins suggests a nutritional causation (see *Morbidity and Mortality Weekly Report* and the report of the Cuban Neuropathy Field Investigation Team, cited in the References). Shortly thereafter, Plant and colleagues reported on a similar outbreak of optic and peripheral neuropathy from Tanzania.

The clinical descriptions from these varied sources are not entirely uniform, but certain features are common to all of them and occur with sufficient frequency to allow the delineation of the neurologic syndrome; it appears to be identical to the one described by Strachan. The core disorder is an affection of the peripheral and optic nerves. The former consists mainly of sensory symptoms and signs, and the latter is characterized by the subacute evolution of failing vision, which, if untreated, may progress to complete blindness and pallor of the optic discs. Deafness and vertigo are generally uncommon, but in some outbreaks among prisoners of war these symptoms were frequent enough to earn the epithet “camp dizziness.” In all these respects the syndrome differs from beriberi. Along with the neurologic signs there may be varying degrees of stomatoglossitis, corneal degeneration, and genital dermatitis (the orogenital syndrome). These mucocutaneous lesions are unlike those of Pellagra and riboflavin deficiency.

There have been only a few neuropathologic studies of this syndrome. Aside from the changes in the papillomacular bundle of the optic nerve, which are similar to the deficiency amblyopia discussed above, the most consistent abnormality has been a loss of myelinated fibers in each column of Goll adjacent to the midline. Fisher has interpreted this change to indicate a degeneration of the central processes of the bipolar sensory neurons of the dorsal root ganglia. The fact that the primary sensory neuron is the main site of the neuropathic disorder is consistent with the predominantly sensory symptomatology. The present authors find it difficult to draw a sharp dividing line between the nutritional peripheral (and optic) neuropathy described above and the Strachan syndrome.

**The Neurologic Manifestations of Vitamin B₁₂ Deficiency**

The spinal cord, brain, optic nerves, and peripheral nerves may all be affected by vitamin B₁₂ (cobalamin) deficiency, giving rise to one of the classic neurologic syndromes. The spinal cord is usually affected first and often exclusively. The term *subacute combined degeneration* (SCD) is customarily reserved for the spinal cord lesion of vitamin B₁₂ deficiency and serves to distinguish it from other types of spinal cord disease that happen to involve the posterior and lateral columns (loosely referred to as *combined system disease*). Whether the peripheral neuropathy is a primary component of the disease or is secondary to damage of the fibers of entry in the dorsal cord has been debated, but the available pathologic evidence favors the former.

The hematologic effects of vitamin B₁₂ deficiency—i.e., *pernicious anemia*—and its neurologic manifestations are distinctive insofar as they usually result not from a dietary lack of vitamin B₁₂ but from the failure to transfer minute amounts of this nutrient across the intestinal mucosa—“starvation in the midst of plenty,” as Castle aptly put it. In the classic disease, this failure derives from the chronic absence of an intrinsic factor, which is secreted (along with hydrochloric acid) by the parietal cells of the gastric mucosa and transports cobalamin (extrinsic factor in the diet) to the ileum, where it is absorbed into the portal system. This is referred to as a *conditioned deficiency*, since it is conditional on the lack of an intrinsic factor.

The hematologic and neurologic manifestations of vitamin B₁₂ deficiency also occasionally complicate other malabsorptive disorders: celiac sprue; extensive gastric or ileal resections; overgrowth of intestinal bacteria in “blind loops,” anastomoses, diverticula, and other conditions resulting in intestinal stasis; and infestation with cobalamin-metabolizing fish tapeworm (*Diphyllobothrium latum*). Rare instances of vitamin B₁₂ deficiency are observed in lactovegetarians and in infants nursed by mothers de-
icient in vitamin B<sub>12</sub>; vitamin B<sub>12</sub> deficiency may also be due to a rare genetic defect of methylmalonyl coenzyme A (CoA) mutase (Table 41-2).

Here it should also be mentioned that interference with methionine synthetase, a methylcobalamin-dependent enzyme, is produced by chronic exposure to nitrous oxide. A megaloblastic state, as well as the neurologic features of subacute combined degeneration, is induced by this gas. This illness in the modern day arises in operating room personnel (we have seen it in anesthesia nurses), occasionally in dentists, and in abusers of the gas. Whether a pre-existing marginal store of B<sub>12</sub> is a predisposing factor is unknown. Cases of subacute combined degeneration have also been described in patients with marginal B<sub>12</sub> stores who had received nitrous oxide general anesthesia during surgery. Serum B<sub>12</sub> levels are usually in the low normal range, but measurements of methylmalonic acid are elevated (see further on).

**Clinical Manifestations** Symptoms of nervous system disease occur in the majority of patients with pernicious anemia. The patient first notices mild general weakness and paresthesias consisting of tingling, “pins and needles” feelings, or other vaguely described sensations. The paresthesias involve the hands and feet, more often the former, and tend to be constant and steadily progressive and the source of much distress. As the illness progresses, the gait becomes unsteady and stiffness and weakness of the limbs, especially of the legs, develop. If the disease remains untreated, an ataxic paraplegia evolves, with variable degrees of spasticity.

Early in the course of the illness, when only paresthesias are present, there may be no objective signs. Later, examination discloses a disorder of the posterior and lateral columns of the spinal cord, predominantly of the former. Loss of vibration sense is by far the most consistent sign; it is more pronounced in the feet and legs than in the hands and arms and frequently extends over the trunk. Position sense is usually impaired as well. The motor signs, usually limited to the legs, include a mild symmetrical loss of strength in proximal limb muscles, spasticity, changes in tendon reflexes, clonus, and extensor plantar responses. At first, the patellar and Achilles reflexes are found to be diminished as frequently as they are increased; they may even be absent. With treatment, the reflexes may return to normal or become hyperactive. The gait at first is predominantly ataxic, later ataxic and spastic.

Loss of superficial sensation below a segmental level on the trunk may occur in isolated instances, but such a finding should suggest the alternative possibility of some other disease of the spi-

nal cord. However, two of our patients have described a band-like sensation around the thorax. The defect of cutaneous sensation may take the form of impaired tactile, pain, and thermal sensation over the limbs in a distal distribution, implicating the small fibers of the peripheral nerves or the spinothalamic tracts, but such findings are also relatively uncommon. The Lhermitte phenomenon (paresthesias down the spine or across the shoulders induced by rapid flexion of the neck) is a common finding if sought.

The nervous system involvement in subacute combined degeneration is roughly symmetrical, and sensory disturbances precede the motor ones; predominantly motor involvement from the beginning and a definite asymmetry of motor or sensory findings maintained over a period of weeks or months should always cast doubt on the diagnosis.

Mental signs are said to be frequent, ranging from irritability, apathy, somnolence, suspiciousness, and emotional instability to a marked confusional or depressive psychosis or intellectual deterioration. Lindenbaum and coworkers have reported cases in which neuropsychiatric symptoms, responsive to vitamin B$_{12}$, were present without spinal cord or peripheral nerve abnormalities. In our clinical material, symptoms of dementia have not been frequent and always followed the spinal cord disorder.

Visual impairment due to optic neuropathy may occasionally be the earliest or sole manifestation of pernicious anemia; examination discloses roughly symmetrical centrocecal scotomata and optic atrophy in the most advanced cases (page 215). The fact that visual evoked potentials may be abnormal in vitamin B$_{12}$-deficient patients without clinical signs of visual impairment suggests that the visual pathways may be affected more often than is evident from the neurologic examination alone. A small number of patients have symptoms of autonomic dysfunction, including urinary sphincteric symptoms and impotence.

The CSF is usually normal; in some cases there is a moderate increase in protein. The EMG shows slowing of sensory conduction or reduced-amplitude sensory potentials. Almost always, according to Hemmer and colleagues, somatosensory evoked potentials reveal delayed conduction or absent responses; these changes are known to recover with treatment. Quite remarkable, as these authors indicate, is the finding on MRI of a T2 signal change that demarcates the posterior columns of the cord, as shown in Fig. 41-1. In two of our cases, these have taken the form of well-defined linear changes within the posterior columns on axial scans of the cervical cord.

Neuropathologic Changes The pathologic process takes the form of a diffuse though uneven degeneration of white matter of the spinal cord and occasionally of the brain. The earliest histologic event is a swelling of myelin sheaths, characterized by the formation of intramyelinic vacuoles and separation of myelin lamellae. This is followed by a coalescence of small foci of tissue destruction into larger ones, imparting a vacuolated, sieve-like appearance to the tissue—an appearance also observed in the myelopathy of AIDS and rarely in lupus erythematosus. The myelin sheaths and axis cylinders are both involved in the degenerative process, the former more obviously and perhaps earlier and more severely than the latter. There is relatively little fibrous gliosis in the early lesions, but in more chronic ones, particularly those in which considerable tissue is destroyed, the gliosis is pronounced. The changes begin in the posterior columns of the lower cervical and upper thoracic segments of the cord and spread from this region up and down the cord as well as forward into the lateral and anterior columns. The lesions are not limited to specific systems of fibers within the posterior and lateral funiculi but are scattered irregularly through the white matter. For this reason, the term combined system disease, which is often used loosely to designate the myelopathy of pernicious anemia, is a less appropriate term than subacute combined degeneration.

In rare instances, foci of spongy degeneration are found in the optic nerves and chiasm and in the central white matter of the brain (Adams and Kubik). The peripheral nerves may show a loss of myelin, but there is no unequivocal evidence that axons are significantly affected.

It has been shown by Victor and Laureno that monkeys sustained on a vitamin B$_{12}$-deficient diet for a prolonged period develop neuropathologic changes indistinguishable from those of subacute combined degeneration in humans (Agamanolis et al). The time required for the production of central nervous system changes in monkeys—33 to 45 months—is comparable to the time required to deplete the vitamin B$_{12}$ stores of patients with pernicious anemia in whom parenteral vitamin B$_{12}$ therapy had been discontinued. It is noteworthy that vitamin B$_{12}$-deprived monkeys

Figure 41-1. Sagittal spinal T2-weighted MRI in subacute combined degeneration showing signal changes in the posterior columns. The patient had markedly reduced vibration and position sense and a Romberg sign; the tendon reflexes were preserved and there were no corticospinal tract or peripheral nerve signs. (Courtesy of Dr. James Corbett.)
do not become anemic, despite the prolonged period of vitamin B\textsubscript{12} deficiency. Also, in distinction to the human condition, involvement of the optic nerves is particularly severe in the monkey and probably precedes the degeneration of the spinal cord. The optic nerve lesions appear first in the papillomacular bundles, in the retrolubar portions of the nerves; it subsequently spreads beyond the confines of this bundle and caudally in the optic nerves, chiasm, and tracts. These changes are much the same as those of “tobacco-alcohol amblyopia” (see above). The peripheral nerves were not affected in the experimentally produced vitamin B\textsubscript{12} deficiency.

The paresthesias, impairment of deep sensation, and ataxia are due to lesions in the posterior columns. Weakness, spasticity, increased tendon reflexes, and Babinski signs depend on involvement of the corticospinal tracts. The spinothalamic tracts may rarely be involved in the pathologic process, which explains the occasional finding of a sensory level for pain and temperature on the trunk, as already noted. The distal and symmetrical impairment of superficial sensation and loss of tendon reflexes that occur in some patients are best explained by involvement of peripheral nerves and are reflected in nerve conduction studies (see further on, under “Diagnosis”).

**Pathogenesis**  
*Methylcobalamin* is an essential cofactor in the conversion of homocysteine to methionine. An impairment of this reaction due to a deficiency of cobalamin is thought to cause a failure of DNA synthesis, accounting for the hematologic abnormalities and particularly for the production of megaloblasts. However, since neurons do not divide, this sequence of chemical events does not explain the central nervous system abnormalities. One of the better-understood functions of vitamin B\textsubscript{12} is its role as a co-enzyme in the methylmalonyl-CoA mutase reaction. In this reaction, which is a key step in propionate metabolism, methylmalonyl-CoA is transformed to succinyl-CoA, which subsequently enters the Krebs cycle. A lack of the cobalamin-dependent enzyme methylmalonyl-CoA mutase leads to the accumulation of methylmalonyl-CoA and its precursor, propionyl-CoA. According to this theorized mechanism, propionyl-CoA displaces succinyl-CoA, which is the usual primer for the synthesis of even-chain fatty acids; this results in the anomalous insertion of odd-chain fatty acids into membrane lipids, such as are found in myelin sheaths. Conceivably this biochemical abnormality underlies the lesions of myelinated fibers that characterize the disease. However, Carmel and associates have described a hereditary form of cobalamin deficiency in which methylmalonyl-CoA mutase activity was normal, despite the presence of typical neurologic abnormalities. In their view, the primary failure is one of methylation of homocysteine to methionine, i.e., a failure of the methionine synthetase reaction, for which the coenzyme methylcobalamin is necessary.

Evidence for the latter view comes also from the observations, mentioned earlier, that prolonged administration of nitrous oxide (N\textsubscript{2}O) may produce not only megaloblastic changes in the bone marrow (Amess et al) but also a sensorimotor polyneuropathy, often combined with signs of involvement of the posterior and lateral columns of the spinal cord (Layzer). Probably N\textsubscript{2}O produces its effects by inactivating the methylcobalamin-dependent enzyme methionine synthetase. These and other hypotheses are discussed by Jandl, Carmel and colleagues, and Beck.

The role of folate deficiency in the genesis of SCD is less certain. One known clinical mistake has been to treat pernicious anemia by giving folic acid; this corrects the anemia but may worsen or even evoke the spinal cord lesions. There are, nevertheless, a few reported examples of cerebral and spinal cord lesions indistinguishable from those due to vitamin B\textsubscript{12} deficiency in patients with defective folate metabolism—both in adults with acquired deficiency (Pincus) and in children with an inborn metabolic error (Clayton et al).

**Diagnosis**  
The main differential diagnostic considerations of the combined sensory and motor features are cervical spondylosis (page 1073), multiple sclerosis of the cervical cord (page 778), rareries such as the female carrier state of adrenoleukodystrophy (adrenomyeloneuropathy, page 836), and non-B\textsubscript{12}—deficient combined system disease (page 1078). The last of these refers to an obscure myelopathic process that affects the posterior and lateral columns subacutely but is unassociated with any form of B\textsubscript{12} deficiency or related enzyme derangement. Recent reports suggest that this process may be the result of an incompletely understood acquired type of copper deficiency. It has been as frequent, in our cases, as the classic type due to B\textsubscript{12} deficiency. This entity is mentioned on page 1078 with other diseases of the spinal cord.

The chief obstacle to early diagnosis is the lack of parallelism that may exist between the hematologic and neurologic signs, occurring particularly in patients who have taken dietary or medicinal folate. Anemia may also at times be absent, sometimes for many months, even in patients who have not taken folate. In a retrospective study of 141 patients with neuropsychiatric abnormalities due to cobalamin deficiency, there were 19 patients in whom both the hematocrit and mean red blood cell volume were normal (Lindenbaum et al); in these patients, subtle morphologic abnormalities—hypersegmented polymorphonuclear leukocytes and megaloblastosis in bone marrow smears—were almost always found if carefully sought.

**Laboratory Diagnosis**  
Serum cobalamin should be measured whenever the diagnosis of vitamin B\textsubscript{12} deficiency is in question. Microbiologic assay (using *Euglena gracilis*) is the most accurate measurement, but the method is time-consuming and cumbersome and has been largely replaced by a commercial radioisotope dilution assay (the inexpensive chemiluminescence assay is an alternative but slightly less dependable). With the radioassay, a serum B\textsubscript{12} level of less than 100 pg/mL is usually associated with neurologic symptoms and signs of vitamin B\textsubscript{12} deficiency. A level below 200 pg/mL that is unassociated with symptoms calls for further investigation of cobalamin deficiency. However, even serum levels of 200 to 300 pg/mL may still be associated (in 5 to 10 percent of cases) with cobalamin deficiency. High serum concentrations of cobalamin metabolites—methylmalonic acid (normal range, 73 to 271 mmol/L) and homocysteine (normal range, 5.4 to 16.2 mmol/L) are probably the most reliable indicators of an intracellular cobalamin deficiency and can be used to corroborate the diagnosis (Allen et al; Lindenbaum et al). It must be emphasized that the serum cobalamin level is not a measure of total body cobalamin. In a patient who stops absorbing ingested cobalamin, the serum levels may remain in the normal range for a long time despite decreasing tissue reserves. In patients who have received vitamin B\textsubscript{12} parenterally, the two-stage Schilling test is a more reliable indicator of cobalamin deficiency, since it uncovers a defect in absorption of the vitamin; however, the Schilling test has been supplanted for routine diagnosis by the measurement of antibodies to intrinsic factor and parietal cells.

Achlorhydria is almost invariably present in patients with pernicious anemia; its presence can be detected by measuring the se-
rum gastrin level. Antibodies to gastric parietal cells are also present in as many as 90 percent of patients with cobalamin deficiency, but this test often yields false-positive results. The finding of serum antibodies against intrinsic factor is diagnostically specific but demonstrable in only 60 percent of cases in most series.

Low cobalamin levels with or without the clinical signs of deficiency may occur in patients with atrophic gastritis or after subtotal gastrectomy. The malabsorption in such cases is thought to be due to a failure to extract cobalamin from food rather than a failure of the intrinsic factor mechanism (“food-cobalamin malabsorption”); since the absorption of free cobalamin is normal, the Schilling test is unimpaired (Carmel). Infection of the gastric mucosa with *Helicobacter pylori* has been implicated in some cases. There are also inherited defects in the gene for intrinsic factor that render it ineffective.

The results of nerve conduction tests have varied in vitamin B₁₂-deficient patients. Early in the course of SCD, nerve conduction may be normal, but in our experience most patients with neurologic symptoms have slowing of distal sensory conduction; others have found reduced amplitudes and minor signs of denervation, suggestive of axonal change. In patients with normal peripheral nerve studies, the somatosensory evoked potentials may show abnormalities attributable to central conduction delays, implicating the posterior columns as the cause of the sensory symptoms (Fine and Hallett). In advanced cases, motor conduction and late responses may be affected to a slight degree. These ambiguities reflect the inconsistent and poorly understood role of the peripheral neuropathic component in this disease.

As already mentioned, the MRI may show lesions in the posterior columns, particularly extending through the cervical and upper thoracic cord, and less often, in the lateral columns. The frequency of these findings, however, is not known, and their absence cannot be considered evidence against the diagnosis.

**Treatment**

The diagnosis of SCD demands the administration of vitamin B₁₂ and the continuation of treatment for a long period or the rest of the patient’s life. In cases of pernicious anemia, the patient is given 1000 μg of cyanocobalamin or hydroxycobalamin intramuscularly each day for several days. The usual approach has been to repeat the injection weekly for a month and then monthly for the remainder of the patient’s life. Although most of the injected cobalamin is excreted, these patients must be flooded with the vitamin because the repletion of cobalamin tissue stores is a direct function of the dose.

In recent years, however, the notion that forms of B₁₂ deficiency must be circumvented by parenteral administration has been questioned and the use of oral cobalamin 500 to 1000 μg daily has been suggested as an alternative for maintenance treatment. Several studies indicate the effectiveness of this approach in elderly patients with poor B₁₂ absorption and in persons with limited diets, such as vegans, but we would express reservation regarding the use of oral replacement in the treatment of pernicious anemia with neurologic manifestations.

The most important factor influencing the response to treatment is the duration of symptoms before treatment is begun; age, gender, and the degree of anemia are relatively unimportant factors. The greatest improvement occurs in those patients whose disturbance of gait has been present for less than 3 months; recovery may be complete if therapy is instituted within a few weeks after the onset of symptoms. All neurologic symptoms and signs may improve, mostly during the first 3 to 6 months of therapy, and then at a slower tempo, during the ensuing year or even longer. In practically all instances, there is some degree of improvement after treatment, although sometimes, in cases of longest duration, the best that can be accomplished is an arrest of progression.

**Other Neurologic Disorders Due to Deficiencies in B Vitamins**

**Pyridoxine (Vitamin B₆) Deficiency**

A special type of nutritional polyneuropathy is encountered in tuberculous patients as a complication of treatment with isonicotinic acid hydrazide (INH; isoniazid). In the recent past, a similar neuropathy was observed in hypertensive patients treated with hydralazine.

The occurrence of a neuropathy due to INH was recognized in the early 1950s, soon after the introduction of this drug for the treatment of tuberculosis. The neuropathy was characterized by paresthesias and burning pain of the feet and legs, followed by weakness of these parts and loss of ankle reflexes. Rarely, with continued use of the drug, the hands were affected as well. The nature of INH-induced neuropathy was clarified by Biehl and Villett. They found that the administration of isoniazid results in a marked excretion of pyridoxine and that the administration of pyridoxine in conjunction with INH prevented the development of neuropathy. As a result of this simple preventive measure, very few examples of INH-induced neuropathy are now observed. Hydralazine, closely related in structure to INH, causes the formation of pyridoxal-isoniazid complexes (hydrazones), which make pyridoxal (the main form of vitamin B₆) unavailable to the tissues. The neuropathy responds favorably to discontinuation of the drug and the administration of pyridoxine.

Severe pyridoxine deficiency in animals and humans also causes seizures. This was first observed in swine by Swank and Adams and later in infants who were maintained on a milk formula lacking in pyridoxine. A pyridoxine-responsive seizure disorder of the neonatal period is discussed on page 288.

**Pyridoxine Toxicity**

Paradoxically, the consumption of large amounts of pyridoxine (by food and vitamin faddists) may also cause a sensory peripheral neuropathy or ganglionopathy (Schaumburg et al; Albin et al). There is no weakness; the symptoms, including ataxia and areflexia, are purely sensory and can be quite disabling. Symptoms may extend to the trunk, scalp, and face. Improvement is the rule when the drug is withdrawn. This disorder is probably due to the direct toxic effect of pyridoxine on dorsal root ganglion cells.

**Pantothenic Acid Deficiency**

A predominantly sensory neuropathy has also been induced, again in swine, by Swank and Adams and later in humans by a deficiency of pantothenic acid (a constituent of coenzyme A), as reported by Bean et al. In some patients the administration of pantothenic acid has allegedly reversed the painful dysesthesias of the “burning foot” syndrome.

**Riboflavin Deficiency**

Whether or not riboflavin deficiency leads to neurologic symptoms has been controversial. In the past, there were claims that glossitis, cheilosis, and neuropathy were due to riboflavin deficiency, but its effects were never isolated. Antozzi and coworkers have reported that a metabolic disorder similar to the Reye syndrome can be caused by riboflavin deficiency and is correctable by administration of riboflavin alone. The affected infants were hypoglycemic, hypotonic, and episodically weak and
unresponsive. Antozzi and colleagues also recorded instances of disease in older children and adults manifest as a type of lipid storage polymyopathy due to either a deficiency or malabsorption of riboflavin. Presumably a disorder of flavin metabolism had caused an impairment of both beta oxidation of fatty acids and respiratory chain I and II complexes. Serum creatine phosphate was normal in these individuals, but carnitine was reduced. The oral administration of 200 mg of riboflavin and 4 g of carnitine per day relieved the symptoms. We have had no experience with such cases.

**Folate Deficiency** Despite the frequency of folic acid deficiency and its hematologic effects, its role in the pathogenesis of nervous system disease has also not been established beyond doubt (see reviews by Crellin et al and by Carney). The polyneuropathy that occasionally complicates the chronic administration of phenytoin has also been attributed, on uncertain grounds, to folate deficiency. Botz and colleagues have described a group of 10 patients with sensorimotor polyneuropathy (4 also had spinal cord disease) presumably due to intestinal malabsorption; all of the patients improved over several months while receiving large doses of folic acid. This experience is unique, however. The possible role of folate deficiency in the pathogenesis of spinal cord disease has been mentioned above in relation to vitamin B12 deficiency, and its putative role in psychiatric disease has been discussed by Carney. If such cases of folate deficiency, subacute combined degeneration, or mental changes do occur, they must be rare.

In summary, it has been well established that polyneuropathy may be caused by a deficiency of at least four B vitamins—thiamine (probably in concert with other vitamin deficiencies), pyridoxine, pantothenic acid, and vitamin B12—and by an extreme excess of pyridoxine. That a deficiency of riboflavin causes lesions of the central or peripheral nervous system has not been proved in our opinion.

**Disorders Due to Deficiencies of Fat-Soluble Vitamins**

**Vitamin E Deficiency** This is of two types: a defect in intestinal absorption and an inherent hepatic enzyme deficiency that blocks incorporation of the vitamin into lipoprotein. A rare neurologic disorder of childhood, consisting essentially of spinocerebellar degeneration in association with polyneuropathy and pigmentary retinopathy, has been attributed to a deficiency of vitamin E consequent to prolonged intestinal fat malabsorption (Muller et al; Satya-Murti et al). The same mechanism has been proposed to explain the neurologic disorders that sometimes complicate abetalipoproteinemia (page 827), fibrocystic disease (Sokol et al), celiac sprue disease (page 977), and extensive intestinal resections (Harding et al). Vitamin E deficiency has also been observed in young children with chronic cholestatic hepatobiliary disease (Rosenblum et al). Ataxia, loss of tendon reflexes, ophthalmoplegia, proximal muscle weakness with elevated serum creatine kinase, and decreased sensation are the usual manifestations. These symptoms are referable to parts of the nervous system and musculature that are found to be diseased in animals deprived of vitamin E—degeneration of Clarke’s columns, spinocerebellar tracts, posterior columns, nuclei of Goll and Burdach, and sensory roots (Nelson et al). Local differences in the natural concentration of vitamin E in various parts of the nervous system and musculature are believed to account for the distribution of the lesions. In affected children, neurologic function improves after long-term daily supplementation with high doses of vitamin E.

In recent years there have been several reports of an inherited form of spinocerebellar degeneration attributable to an inherited but conditioned vitamin E metabolism that may closely mimic the phenotype of Friedreich ataxia (“familial isolated vitamin E deficiency”). In these patients, absorption and transport of vitamin E to the liver is normal but hepatic incorporation of tocopherol (the active form of vitamin E) into very-low-density lipoproteins is defective (Traber et al). The abnormality has been traced to a mutation in the gene for the tocopherol transfer protein, located on chromosome 8q (Gotoda et al). In a sense this is a vitamin deficiency conditioned by a genetic mutation. An important feature of these cases is that chronic oral administration of large doses of vitamin E can halt and even reverse progression of the ataxia (Gabsi et al).

**Vitamins A and D** Disorders due to a lack or excess of these fat-soluble vitamins have been reported, but they are rare. Vitamin A deficiency sometimes occurs with malabsorption syndromes, causing impairment of vision. *Excess of vitamin A* in children or adults may result in the syndrome of *pseudotumor cerebri* (page 538). Vitamin D deficiency has been associated with hypoparathyroidism or a malabsorption state that leads to hypocalcemia, proximal muscle weakness, and rickets.

**DISEASES OF THE NERVOUS SYSTEM OF PROBABLE BUT UNPROVEN NUTRITIONAL ORIGIN**

The disorders comprised by this category, as the above title implies, have only an uncertain relationship to nutritional deficiency. They are found mainly in alcoholics, but their relationship to alcohol is probably not fundamental, since each has also been observed in nonalcoholic patients. The belief that these disorders are nutritional in origin is based on certain indirect evidence: (1) Usually, a prolonged period of undernutrition associated with a significant loss of weight precedes the neurologic illness. In such cases that are associated with alcoholism, the amount of alcohol consumed need not be large, but the dietary deprivation is always severe. (2) Examination at the onset of the illness frequently discloses general physical evidence of undernutrition as well as the presence of neurologic disorders of known nutritional etiology. (3) Certain attributes of the neuropathologic changes—namely their subacute evolution, symmetry, and constancy of localization—are precisely the features that characterize neurologic disorders of known nutritional etiology. (4) The same syndromes are observed occasionally in nonalcoholics under conditions of dietary depletion. (5) There is at least a partial response to correction of the nutritional impairment.

**“Alcoholic” Cerebellar Degeneration**

This term refers to a common and uniform type of degeneration of the vermis and anterior lobes of the cerebellum in alcoholics. Its incidence is about twice that of Wernicke disease, but unlike the latter, it is considerably more frequent in men than in women. It is characterized clinically by a wide-based stance and gait, varying degrees of instability of the trunk, and ataxia of the legs, the arms being affected to a lesser extent and often not at all. Nystagmus...
and dysarthria are infrequent. In addition to an ataxic (intention) tremor, there may be a tremor of the fingers or hands resembling one of the two types of parkinsonian tremor but appearing only when the limbs are placed in certain sustained postures. Mauritz and coworkers have demonstrated that the instability of the trunk in these cases consists of a specific 3-Hz rhythmic swaying in the anteroposterior direction; by contrast, patients with lesions of the cerebellar hemispheres show only slight postural instability without directional preponderance.

In most cases, the cerebellar syndrome evolves over a period of several weeks or months, after which it remains unchanged for many years. In others, it develops more rapidly or more slowly, but in these cases also the disease eventually stabilizes. Occasionally, the cerebellar disorder progresses in a saltatory manner, the symptoms worsening in relation to a severe infectious illness or an attack of delirium tremens.

The pathologic changes consist of a degeneration of all the neurocellular elements of the cerebellar cortex but particularly of the Purkinje cells in the anterior and superior aspects of the vermis. The cerebellar atrophy is readily visualized by computed tomography (CT) (Fig. 41-2) and MRI.

Two particular forms of this syndrome have not been emphasized sufficiently. In one, the clinical abnormalities are limited to an instability of station and gait, individual movements of the limbs being unaffected. The pathologic changes in such cases are restricted to the anterosuperior portions of the vermis. A second type is strikingly acute but transient. Here, except for their reversibility, the cerebellar symptoms are identical to those that characterize the chronic, fixed form of the disease. In this transient type, the derangement is only one of function (“biochemical lesion”) and has probably not progressed to the point of fixed structural changes. These forms of cerebellar disease, and particularly the restricted and reversible varieties, cannot be distinguished from the cerebellar manifestations of Wernicke disease either on pathologic or on clinical grounds. It is our opinion that the cerebellar ataxia of Wernicke disease and that referred to as alcoholic cerebellar degeneration are based on the same disease process, the former term being applicable when the cerebellar abnormalities are associated with ocular and mental signs and the latter when the cerebellar syndrome stands alone. Alcoholic cerebellar degeneration is in all likelihood due to nutritional deficiency and not to the toxic effects of alcohol or other causes, for reasons already indicated. Insofar as the cerebellar ataxia usually improves to some extent under the influence of thiamine alone (see above, under “Wernicke-Korsakoff Syndrome”), it is likely that a deficiency of this vitamin is in whole or part responsible for the cerebellar lesion, but this has not been proven.

**Marchiafava-Bignami Disease**

(Primary Degeneration of the Corpus Callosum)

In 1903, the Italian pathologists Marchiafava and Bignami described a unique alteration of the corpus callosum in three alcoholic patients. In each case, coronal sectioning of the fixed brain disclosed a pink-gray discoloration of the central portion of the corpus callosum throughout the longitudinal extent of this structure. Microscopically, the lesion proved to be confined to the middle lamina (which makes up about two-thirds of the thickness of the corpus callosum), in which there was a loss of myelin, and to some degree, of the axis cylinders; macrophages were abundant in the altered zone, and astrocytic proliferation had followed. The clinical observations in these patients were few and incomplete. In 1907, Bignami described a case in which the corpus callosum lesion was accompanied by a similar lesion in the central portion of the anterior commissure.

These early reports were followed by a spate of articles that confirmed and amplified the original clinical and pathologic findings. By 1922 about 40 cases of this disorder had been described in the Italian literature (Mingazzini). With one exception, all the reported cases were in males, and all of these men were insatiable drinkers. They drank red wine for the most part but other forms of liquor as well. Beginning in 1936, with the report of King and Meehan, the disease came to be recognized throughout the world, and the notions that it had a predilection for drinkers of red wine and a special racial predisposition or geographic locale were abandoned.
Pathologic Features Marchiafava-Bignami disease is more readily defined by its pathologic than its clinical features. The principal alteration is in the middle portion of the corpus callosum, which on gross examination appears somewhat rarefied and sunken and reddish or gray-yellow in color, depending on its age. In the anterior portion of the corpus callosum, the lesion tends to be more severe in the midline than in its lateral parts; in the splenium, however, the opposite may pertain. The most chronic lesion takes the form of a centrally placed gray cleft or cavity, with collapse of the surrounding tissue and reduction in thickness of the corpus callosum. Microscopically, corresponding to the gross lesions, one observes clearly demarcated zones of demyelination, with variable involvement of the axis cylinders and an abundance of fatty macrophages with gliosis at the margins. Inflammatory changes are absent.

Infrequently, lesions of a similar nature are found in the central portions of the anterior and posterior commissures and the brachia pontis. These zones of myelin destruction are always surrounded by a rim of intact white matter. The predilection of this disease process for commissural fiber systems has been stressed, but it is certainly not confined to these fibers. Symmetrically placed lesions have been observed in the columns of Goll, superior cerebellar peduncles, and cerebral hemispheres, involving the central semiovale and extending, in some cases, into the adjacent convolutional white matter. As a rule, the internal capsule and corona radiata, subcortical arcuate fibers, and cerebellum are spared. In several cases, the lesions of deficiency amylodgia (see above) have been added; in others, the lesions of Wernicke disease.

Many of the reported cases, as first pointed out by Jequier and Wildi, have involved cortical lesions of a special type: the neurons in the third layer of the frontal and temporal lobe cortices had disappeared and were replaced by a fibrous gliosis. Morel, who first described this cortical laminar sclerosis, did not observe its association with Marchiafava-Bignami disease. However, when Jequier and Adams reviewed his original cases (unpublished), all had Marchiafava-Bignami disease. In a subsequent report by Delay and colleagues comprising 14 cases of cortical laminar sclerosis, the cortical lesion was also consistently associated with a corpus callosum lesion. We believe the cortical lesions are best explained as secondary to the callosal degeneration.

Clinical Features The disease affects persons in middle and late adult life. With few exceptions, the patients have been males and severe chronic alcoholics. The clinical features of the illness are otherwise quite variable, and a clear-cut syndrome of uniform type has not emerged. Many patients have presented in a state of terminal stupor or coma, precluding a detailed neurologic assessment. In others, the clinical picture was dominated by the manifestations of chronic inebriation and alcohol withdrawal—tremor, seizures, hallucinosis, and delirium tremens. In some of these patients, following the subsidence of the withdrawal symptoms, no signs of neurologic disease could be elicited, even in the end stage of the disease, which lasted for several days to weeks. In yet another group, a progressive dementia has been described, evolving slowly over a 3- to 6-year period before death. Emotional disorders leading to acts of violence, marked apathy, moral perversions, and sexual misdemeanors have been noted in these patients; dysarthria, slowing and unsteadiness of movement, transient sphincteric incontinence, hemiparesis, and apractic or aphasis disorders were superimposed in others. The last stage of the disease is characterized by physical decline, seizures, stupor, and coma. An impressive feature of these varied neurologic deficits in some patients has been their tendency toward remission when nutrition was restored.

In two cases that have come to our attention, the clinical manifestations were essentially those of bilateral frontal lobe disease: motor and mental slowness, apathy, prominent grasping and sucking reflexes, gegenhalten, incontinence, and a slow, hesitant, wide-based gait. In both of these cases, the neurologic abnormalities evolved over a period of about 2 months, and both patients recovered from these symptoms within a few weeks of hospitalization. Death occurred several years later as a result of liver disease and subdural hematoma, respectively. In each case, autopsy disclosed an old lesion typical of Marchiafava-Bignami disease confined to the central portion of the most anterior parts of the corpus callosum, but one had to look closely to see the gray line of gliosis.

In view of the great variability of the clinical picture and the obscuration in many patients of subtle mental and neurologic abnormalities by the effects of chronic inebriation and other alcoholic neurologic disorders, the diagnosis of Marchiafava-Bignami disease is understandably difficult. In fact, it is rarely made during life, but the CT scan and MRI have disclosed some typical but unsuspected examples (see Kawamura et al). In some cases studied sequentially, MRI disclosed demyelination, swelling, and necrosis of the corpus callosum with extension toward the subcortical white matter. In rare cases these findings have reversed over time after vitamin therapy, leaving residual callosal atrophy (Gambini). The occurrence, in a chronic alcoholic, of a frontal lobe syndrome or a symptom complex that points to a diagnosis of frontal or corpus callosum tumor but in whom the symptoms remit should suggest the diagnosis of Marchiafava-Bignami disease. The image appearance may be mistaken for multiple sclerosis or gliomatosis cerebri.

Pathogenesis and Etiology Originally, Marchiafava-Bignami disease was attributed to the toxic effects of alcohol, but this is an unlikely explanation in view of the prevalence of alcoholism and the rarity of corpus callosum degeneration. Further, the distinctive callosal lesions have not been observed with other neurotoxins. Very rarely, undoubted examples of Marchiafava-Bignami disease have occurred in abstainers, so that alcohol cannot be an indispensable factor. A nutritional etiology has been invoked, for the reasons given earlier, but the factor that is deficient has not been determined. This view is underscored by reports of improvement in a few but not all cases following administration of thiamine. The mechanisms involved in the selective demyelination and noninflammatory necrosis of particular areas of white matter remain to be elucidated. Perhaps, when its mechanism becomes known, Marchiafava-Bignami disease, like central pontine myelinolysis (which it resembles histologically), will have to be considered in a chapter other than one on nutritional disease.

Protein-Calorie Malnutrition (PCM) and Mental Retardation

The reader might gather from the foregoing descriptions that the nervous system is rarely affected by nutritional deficiency except when subjected to the influence of chronic inebriation, and then the essential problem is one of dietary imbalance—an inadequacy of B vitamins in the face of an adequate or near adequate caloric intake. It is true that the CNS resists the effects of starvation better than other organs. Nonetheless, there is increasing evidence that severe dietary deprivation during critical phases of brain development may result in permanent impairment of cerebral function and

in mental retardation. Inasmuch as there are an estimated 100 million children in the world who are undernourished and suffer from varying degrees of protein, calorie, and other dietary inadequacies, this is one of the most pressing problems in medicine and society.

Two overlapping syndromes have been defined in malnourished infants and children: kwashiorkor and marasmus. Kwashiorkor is a syndrome of weanling children and is due to protein deficiency; it is manifest by edema (and sometimes ascites), hair changes (sparsity and depigmentation), and stunting of growth. The edema is due to hypoalbuminemia; in addition, there is an abnormal pattern of blood amino acids as well as a fatty liver. Sometimes there are skin changes suggestive of pellagra or riboflavin deficiency. Marasmus is characterized by an extreme degree of cachexia and growth failure in early infancy. Infants with marasmus have usually been weaned early or were never breast-fed. Common to both groups of children is an apathy and indifference to the environment combined with irritability when they are handled or moved. The children are underactive; even after an adequate diet has been instituted, their tendency is to follow with the eyes rather than to move. At one stage of early convalescence, some kwashiorkor children pass through a phase of rigidity and tremor for which there has been no explanation.

As a rule, the clinical signs of polyneuropathy or subacute combined degeneration of the cord are lacking in children with PCM. However, electrophysiologic testing may disclose a reduction of motor nerve conduction velocity and abnormalities of sensory conduction (Chopra et al.). In children with severe degrees of PCM, it is said that there may be evidence, in sural nerve biopsies, of retarded myelination (consistency of only the small myelinated fibers) and segmental demyelination.

Of great interest is whether the children who are rescued from these states of undernutrition by proper feeding are left with an underdeveloped or damaged brain. This subject has been studied extensively in many species of animals, as well as in humans, by clinical, biochemical, and neuropathologic methods. The literature is too large to review here, but excellent critiques have been provided by Winick, Birch and coworkers, Latham, and Dodge and colleagues.

In contrast to the devastating effect of PCM on body growth, brain weight is only slightly reduced. Nevertheless, on the basis of experiments in dogs, pigs, and rats, it is evident that prenatal and early postnatal malnutrition retards cellular proliferation in the brain. All cells are affected, including oligodendroglia, with a proportional reduction in myelin. Also, the process of dendritic branching may be retarded by early malnutrition. A limited number of studies in humans suggest that PCM has a similar effect on the brain during the first 8 months of life. In animals, varying degrees of recovery from the effects of early malnutrition are possible if normal nutrition is re-established during the vulnerable periods. Presumably this is true for humans as well, although proof is difficult to obtain. In every series of severely undernourished infants and young children who have been observed for a period of many
years, a variable proportion has been left scholastically incompetent and mentally backward to a modest degree; the majority recover, however (Galler). Unfortunately, the neurologic and intellectual consequences of PCM have defied accurate assessment because of the difficulty of isolating the effects of severe malnutrition from those of infection, social deprivation, genetic faults, and other factors. The relative importance of these various factors is still under study.

**Nutritional Deficiencies Secondary to Diseases of the Gastrointestinal Tract**

The vitamins known to be essential to the normal functioning of the central and peripheral nervous systems cannot be synthesized by the human organism. Each is ingested as an essential part of the normal diet and absorbed in certain regions of the gastrointestinal tract. Impairment or failure of absorption due to diseases of the gastrointestinal tract gives rise to several malabsorption syndromes, some of which have already been referred to—e.g., malabsorptive vitamin E deficiency. In these diseases, the site of the block in transport from the intestinal lumen varies; it may be at the surface of the enterocytes or at their interface with the lymphatic channels and portal capillaries.

Table 41-2, which is modified from Pallis and Lewis, lists the malabsorptive diseases and their relationships to the intestinal abnormalities. Of all these diseases, celiac sprue (gluten enteropathy) is the most common. The neurologic complications of this disorder, in our experience, have taken the form of a symmetrical, predominantly sensory polyneuropathy, as described on page 1142. However, other complications have been described, notably a progressive cerebellar syndrome with cortical, dentatal, and olivary cell loss. The cerebellar changes may be coupled with a symmetrical demyelination of the posterior columns, producing a spinocerebellar disorder similar to that of vitamin E deficiency, but in the latter case, vitamin E supplementation has no consistent effect. Others have remarked on a high incidence of depression and other psychiatric disturbances in adult patients with celiac sprue, as also discussed in Chap. 40. Unexplained seizures are also said to occur.

Polyneuropathy and subacute combined degeneration of the spinal cord manifesting themselves many years after gastrectomy are encountered only rarely.

The neurology of gastrointestinal disease has been reviewed by Perkin and Murray-Lyon.

**INHERITED VITAMIN-RESPONSIVE NEUROLOGIC DISEASES**

(See Table 41-3 and Chap. 37)

Although humans lack the capacity to synthesize essential vitamin molecules, they are nonetheless able to use them in a series of complex chemical reactions involved in intestinal absorption, transport in the plasma, entry into the organelles of many organs, activation of the vitamin into coenzyme, and finally their interaction with certain specific apoenzyme proteins. This compels consideration of another aspect of nutrition wherein one or more of these steps in vitamin utilization may be defective because of a genetic abnormality. Under these circumstances, the signs of vitamin deficiency result not from vitamin deficiency in the diet but from a genetically deranged control mechanism. In some instances the defect is only quantitative, and by loading the organism with a great excess of the vitamin in question, the biochemical abnormality can be overcome. The aforementioned special type of vitamin E deficiency that results from an inherited inability to incorporate the vitamin into lipoproteins also falls into this category—the diseases of which, being of hereditary type, have already been described in Chap. 37, “The Inherited Metabolic Diseases of the Nervous System.” Rosenberg has listed the most important of these hereditary vitamin-responsive diseases, which we have simplified for the reader in Table 41-3.

CHAPTER 42

ALCOHOL AND ALCOHOLISM

Intemperance in the use of alcohol creates many problems in modern society, the importance of which can be judged by the repeated emphasis they receive in contemporary writings, both literary and scientific. These problems may be divided into three categories: psychologic, medical, and sociologic. The main psychologic issue regards why a person drinks excessively, often with full knowledge that such action will result in physical injury and even death. The medical problem embraces all aspects of alcoholic habitation as well as the diseases that result from the abuse of alcohol. The sociologic problem encompasses all of the effects of sustained drinking on the patient’s work, family, and community. Some idea of the enormity of these problems can be gleaned from figures supplied by the Secretary of Health and Human Services—which indicate that up to 40 percent of medical and surgical patients have alcohol-related problems and that these patients account for 15 percent of all health-care costs, which in 1995 were estimated at 150 billion dollars.

Problems engendered by excessive drinking cannot be separated from one another; the physician must therefore be conversant with all aspects of this subject. Often, admission to a “detoxification” unit or a general hospital or to a psychiatric facility is required, according to the nature of the clinical disorder; and the physician then must depend on the aid of social agencies to help the patient or the patient’s family.

The causation of alcoholism remains obscure, although environmental, cultural, and genetic factors are clearly implicated in certain groups of patients. No single personality type has been shown to predict reliably who will become addicted to alcohol. Similarly, no particular aspect of alcohol metabolism has been found to account for the development of addiction in some individuals and not in others, with the possible exception of aldehyde dehydrogenase (see later). Some persons drink excessively and become alcoholic in response to a profoundly disturbing personal or family problem, but most do not. Alcoholism may develop in response to a depressive illness, more so in women than in men, but far more often depression is a consequence of drinking. Social and cultural influences are undoubtedly important in the genesis of alcoholism, as evidenced, for example, by the remarkably high incidence of alcoholism and drinking problems in the American Indian and Eskimo populations and by the disparity in the prevalence of alcoholism, within a single community, among various ethnic groups. However, no ethnic or racial group and no social or economic class are exempt. The writings of Schuckit and of Mello, listed in the references, provide critical overviews of the many etiologic theories.

The importance of genetic factors in alcoholism has been amply identified. Goodwin and coworkers studied 55 Danish men whose biologic parents were alcoholic and 55 control subjects whose biologic parents were not alcoholic. All of the subjects had been adopted before the age of 5 weeks and had no knowledge of their biologic parenthood. Twenty percent of the offspring of biologic alcoholic parents, but only 5 percent of the control subjects, had become alcoholics by the age of 25 to 29 years. A Swedish adoption study (Bohman) and one in the United States (Cadoret et al) have corroborated these findings. Family studies have disclosed a three- to fourfold increased risk for alcoholism in sons and daughters of alcoholics, and twin studies have shown a twofold higher concordance rate for alcoholism in monozygotic than in dizygotic pairs. Details of these studies can be found in the comprehensive reviews of the genetics of alcoholism by Grove and Cadoret and by Schuckit. The search goes on for a biologic trait, or marker, that would identify those who are genetically vulnerable to the development of alcoholism, but to date none has proved to be sufficiently practical or sensitive to identify all such persons (Reich).

Several surveys have suggested a rate of alcohol dependence of 3 to 5.5 percent of adults. A minimum of 3 percent of deaths in the United States can be attributed to alcohol-related causes. More striking, but not at all surprising, is the fact that alcohol intoxication is responsible for approximately 45 percent of fatal motor vehicle accidents and 22 percent of boating accidents. It requires little imagination to conceive the havoc wrought by alcohol in terms of decreased productivity, increased incidence of suicide, accidents, crime, mental and physical disease, and disruption of family life.

PHARMACOLOGIC AND PHYSIOLOGIC CONSIDERATIONS

Ethyl alcohol, or ethanol, is the active ingredient in beer, wine, whiskey, gin, brandy, and other less common alcoholic beverages. In addition, the stronger spirits contain enantiomeric ethers, which provide flavor but have no important pharmacologic properties, and impurities such as amyl alcohol (fusel oil) and acetaldehyde, which act like alcohol but are more toxic. Contrary to popular opinion with regard to the prevention of Wernicke disease, the content of B vitamins in American beer and other liquors is so low as to have little nutritional value (Davidson).

Alcohol is metabolized chiefly by oxidation, less than 10 percent being excreted chemically unchanged in the urine, perspiration, and breath. The energy liberated by the oxidation of alcohol (7 kcal/g) can be utilized as completely as that derived from the metabolism of other carbohydrates. However, calories from alcohol are empty of nutrients such as proteins and vitamins and cannot be used in the repair of damaged tissue. All ingested alcohol except that metabolized by alcohol dehydrogenase in the stomach wall is carried by the portal system to the liver. Here several enzyme systems can independently oxidize alcohol to acetaldehyde. The most important of these, accounting for 80 to 90 percent of ethanol oxidation in vivo, are alcohol dehydrogenase (ADH) and its isoenzymes. This reaction leads to the formation of acetaldehyde and the reduction of NAD to NADH. A second pathway of lesser importance involves catalase, which is located in the peroxisomes and mitochondria; a third utilizes the “microsomal ethanol oxidizing system” (MEOS), located mainly in the microsomes of the endoplasmic reticulum. The details of the process by which acetaldehyde is metabolized are still not settled. Most likely it is converted by aldehyde dehydrogenase to acetate. Acetaldehyde has a number of unique biochemical effects that are not produced by alcohol alone. Persons who flush easily after ingestion of alcohol (Chinese, Japanese, and other Asians) differ from “nonflushers” with respect to the metabolism of acetaldehyde rather than to the metabolism...
of alcohol. The flushing reaction has been traced to a deficiency of aldehyde dehydrogenase activity (Harada et al). The low rate of alcoholism among Asians is said to be related to the flushing reaction (which is, in effect, a modified alcohol-disulfiram reaction—see further on), but this can hardly be the case, since North American Indians, a group with a high incidence of alcoholism, show the same reaction.

For all practical purposes, once the absorption of alcohol has ended and an equilibrium has been established with the tissues, ethanol is oxidized at a constant rate, independent of its concentration in the blood (about 150 mg alcohol per kilogram of body weight per hour, or about 1 oz of 90-proof whiskey per hour). Actually, slightly more alcohol is metabolized per hour when the initial concentrations are very high, and repeated ingestion of alcohol may facilitate its metabolism, but these increments are of little clinical significance. In contrast, the rate of oxidation of acetaldehyde does depend on its concentration in the tissues. This fact is of importance in connection with the drug disulfiram (Antabuse), which acts by raising the tissue concentration necessary for the metabolism of a certain amount of acetaldehyde per unit of time. The patient taking both disulfiram and alcohol will accumulate an inordinate amount of acetaldehyde, resulting in nausea, vomiting, and hypotension, sometimes so pronounced in degree as to be fatal. Certain other drugs—notably the sulfonylureas, metronidazole, and furazolidone—have effects like those of disulfiram but are less potent.

Alcohol acts directly on neuronal membranes in a manner akin to that of the general anesthetics. These agents, as well as barbiturates and benzodiazepines, are lipid-soluble and are thought to dissolve in the cell membranes (in direct relation to the degree of their lipid solubility). With continued ingestion of alcohol, the neuronal membranes ostensibly “rigidify” and become resistant to the fluidizing effect of alcohol (Chin and Goldstein; Harris et al). It is unlikely, however, that these changes in the physical properties of cell membranes are in themselves sufficient to alter cell function. Probably of greater importance are the effects of alcohol on membrane receptor systems that regulate ion channels, particularly the chloride and calcium channels. One likely site that relates to the acute intoxicating effects of alcohol is a receptor for the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) and its associated chloride-ion channel. Benzodiazepine antagonists appear to block the potentiation by alcohol of GABA-induced chloride flux. Like the GABA-chloride channel, the N-methyl-D-aspartate (NMDA) receptors, which transduce signals carried by glutamate (the major excitatory transmitter in brain), are sensitive to extremely low concentrations of alcohol. There is also evidence that alcohol selectively potentiates serotonin receptor-ion currents, and the activity of this receptor has been implicated in alcohol- and drug-seeking behavior and addiction.

The effect of chronic administration of alcohol is to increase the number of neuronal calcium channels in the cell membrane. Moreover, calcium channel blockers, given during chronic administration, prevent both the increase in neuronal calcium channels and the development of tolerance to alcohol (Dolin and Little). The significance of these findings has been demonstrated by Little and colleagues, who showed that calcium channel blockers, given to chronically intoxicated animals after withdrawal, prevent withdrawal convulsions.

The molecular mechanisms involved in the genesis of alcohol intoxication and tolerance are obviously far more complex than the foregoing remarks would indicate (see reviews by Charness and by Samson and Harris). There is now a vast literature on this subject, much of it contradictory. A unified concept of the role of neurotransmitters and their receptors and modulators in the production of alcohol intoxication and tolerance has yet to emerge. The part played by internal cellular messengers, which have attracted much attention in the field of addiction, is also currently under investigation.

Alcohol functions as a central nervous system (CNS) depressant. Some of the early toxic effects of alcohol, such as garrulousness, aggressiveness, excessive activity, and increased electrical excitability of the cerebral cortex—all of them suggestive of cerebral stimulation—are thought to be due to the inhibition of certain subcortical structures (possibly the highbrainstem reticular formation) that ordinarily modulate cerebrocortical activity. Similarly, the initial hyperactivity of tendon reflexes may represent a transitory escape of spinal motor neurons from higher inhibitory centers. With increasing amounts of alcohol, however, the depressant action involves the cortical as well as other brainstem and spinal neurons. All manner of motor functions—whether the simple maintenance of a standing posture, the control of speech and eye movements, or highly organized and complex motor skills—are adversely affected by alcohol. The movements involved in these acts are not only slower than normal but also more inaccurate and random in character and therefore less well adapted to the accomplishment of specific ends.

Alcohol also impairs the efficiency of mental function by interfering with the speed of perception and the ability to persist in mental processing. The learning process is slowed and rendered less effective. Facility in forming associations, whether of words or of figures, and the ability to focus, sustain attention, and concentrate are reduced. The subject is less versatile in directing thought along new lines appropriate to the problem at hand. Finally, alcohol impairs the faculties of judgment and discrimination and, all in all, the ability to think and reason clearly.

A scale relating various degrees of functional impairment to blood alcohol levels in nonhabituated persons was constructed many years ago by Miles. At a blood alcohol level of 30 mg/dL, a mild euphoria was detectable, and at 50 mg/dL, a mild incoordination. At 100 mg/dL, ataxia was obvious; at 200 mg/dL, there was confusion and a reduced level of mental activity; at 300 mg/dL, the subjects were stuporous; and a level of 400 mg/dL—accompanied by deep anesthesia—was potentially fatal. These figures are valid provided that the alcohol content in the blood rises steadily over a 2-h period.

**Tolerance** It should be emphasized that a scale such as the one previously described has virtually no value in the chronic alcoholic patient, for it does not take into account the adaptation of the organism to alcohol, i.e., the phenomenon of tolerance. It is common knowledge that a habituated person can drink more and show fewer effects than the moderate drinker or abstainer. This phenomenon accounts for the surprisingly large amounts of alcohol that the chronic drinker can consume without showing significant signs of drunkenness. Sober-appearing alcoholics may have blood alcohol levels of 400 to 500 mg/dL. This aspect of tolerance must always be considered in judging the significance of a single estimation of the blood alcohol concentration as an index of functional capacity.

The mechanisms that underlie tolerance and addiction are just beginning to be understood. There is little evidence that an enhanced rate of alcohol metabolism can adequately account for the degree of tolerance observed in alcoholics. An increase of neuronal adaptation to alcohol is a more likely explanation. As mentioned
earlier, theoretically the factors that are operative in this adaptation are the increasing resistance of neuronal membranes to the “fluidizing” effects of alcohol and an increase in the number of neuronal calcium channels in the cell membrane.

**CLINICAL EFFECTS OF ALCOHOL ON THE NERVOUS SYSTEM**

A large number of neurologic disorders are associated with alcoholism. The factor common to all of them, of course, is the abuse of alcohol, but the mechanism by which alcohol produces its effects varies widely from one group of disorders to another and in many cases, the essential problem is one of nutritional deficiency as discussed in the preceding chapter. The classification that follows is based for the most part on known mechanisms.

I. Alcohol intoxication—drunkenness, coma, excitement (“pathologic intoxication”), “blackouts”
II. Abstinence or withdrawal syndrome—tremulousness, hallucinosis, seizures, delirium tremens
III. Nutritional diseases of the nervous system secondary to alcoholism (Chap. 41)
   A. Wernicke-Korsakoff syndrome
   B. Polyneuropathy
   C. Optic neuropathy (“tobacco-alcohol amblyopia”)
   D. Pellagra
IV. Diseases of uncertain pathogenesis associated with alcoholism
   A. Cerebellar degeneration
   B. Marchiafava-Bignami disease
   C. Central pontine myelinolysis
   D. “Alcoholic” myopathy and cardiomyopathy
   E. Alcoholic dementia
   F. Cerebral atrophy
V. Fetal alcohol syndrome
VI. Neurologic disorders consequent upon cirrhosis and portal-systemic shunts (Chap. 40)
   A. Hepatic stupor and coma
   B. Chronic hepaticoencephalopathy
VII. Traumatic brain lesions consequent to intoxication—subdural hematoma, cerebral contusion, etc.

**Alcohol Intoxication**

The usual manifestations of alcohol intoxication are so commonplace that they require little elaboration. They consist of varying degrees of exhilaration and excitement, loss of restraint, irregularity of behavior, loquacity and slurred speech, incoordination of movement and gait, irritability, drowsiness, and, in advanced cases, stupor and coma. There are several complicated types of alcohol intoxication, which are considered below.

**Pathologic Intoxication** Despite what has been said earlier, on rare occasions, alcohol has an exclusively excitatory rather than a sedative effect. This reaction has been referred to in the past as pathologic, or complicated, intoxication and as acute alcoholic paranoid state. Since all forms of intoxication are pathologic, atypical intoxication or idiosyncratic alcohol intoxication are more appropriate designations. Nevertheless, the term pathologic intoxication is still widely used. The boundaries of this syndrome have never been clearly drawn. In the past, variant forms of delirium tremens and epileptic phenomena, as well as psychopathic and criminal behavior, were indiscriminately included. Now the term is generally used to designate an outburst of blind fury with assaultive and destructive behavior. Often the patient is subdued only with difficulty. The attack terminates with deep sleep, which occurs spontaneously or in response to parenteral sedation; on awakening, the patient has no memory of the episode. Lesser degrees are also known wherein the patient, after several drinks, repeatedly commits gross social indiscretions. Allegedly this reaction may follow the ingestion of a small amount of alcohol, but in the patients we have observed the amount has often been substantial. Unlike the usual forms of alcohol intoxication and withdrawal, the atypical form has not been produced in experimental subjects, and the diagnosis depends upon the aforementioned arbitrary criteria.

Pathologic intoxication has been ascribed to many factors, but there are no meaningful data to support any of them. However, an analogy may be drawn between pathologic intoxication and the paradoxical reaction that occasionally follows the administration of barbiturates or other sedative drugs. The few patients we have seen, mostly young men of college age or slightly older, have been docile and seemingly well adjusted when not drinking. Usually, they have avoided alcohol after a first episode of this sort, but there are exceptions.

The main disorders to be distinguished from pathologic intoxication are temporal lobe seizures that occasionally take the form of outbursts of rage and violence and the explosive episodes of violence that characterize the behavior of certain sociopaths. The diagnosis in these cases may be difficult and depends on eliciting the other manifestations of temporal lobe epilepsy or sociopathy. Treatment is discussed below.

**Alcoholic “Blackouts”** In the language of the alcoholic, the term blackout refers to an interval of time, during a period of severe intoxication, for which the patient, when sober, has no memory—even though the state of consciousness, as observed by others, was not grossly altered during that interval. However, a systematic assessment of mental function during the amnesic period has usually not been made. A few observations indicate that it is short-term (retentive) memory, rather than immediate or long-term memory, that is impaired; this feature and the subsequent amnesia for the episode are somewhat reminiscent of the disorder known as transient global amnesia (page 379) but without the incessant questioning and competence in nonmemory mental activities that characterizes the latter.

Blackouts may occur at any time in the course of alcoholism, even during the first drinking experience, and they certainly have happened in persons who never became alcoholic. The salient facts are that there is a degree of intoxication that interferes with the registration of events and the formation of memories during the period of intoxication and that the amount of alcohol consumed in moderate social drinking will rarely produce this effect.

**Alcoholic Stupor and Coma** As has been indicated, the symptoms of alcoholic intoxication are the result of the depressant action of alcohol on cerebral and spinal neurons. In this respect alcohol acts on nerve cells in a manner akin to the general anesthetics. Unlike the latter, however, the margin between the dose of alcohol that produces surgical anesthesia and that which dangerously depresses respiration is a narrow one, a fact that adds an element of urgency to the diagnosis and treatment of alcoholic coma. One must also be alert to the possibility that barbiturates or other sedative-
hypnotic drugs may have potentiated the depressant effects of alcohol. One of the most treacherous situations is traumatic brain injury that is complicated by intoxication, a circumstance that is prone to misinterpretation because of uncertainty as to the main cause of stupor or coma.

**Treatment of Severe Alcohol Intoxication**  
Coma due to alcohol intoxication represents a medical emergency. The main object of treatment is to prevent respiratory depression and its complications as described in Chap. 17. One would like to lower the blood alcohol level as rapidly as possible. The previously favored administration of fructose or of insulin and glucose for this purpose is of little value. Analeptic drugs such as amphetamine and various mixtures of caffeine and picrotoxin are antagonistic to alcohol only insofar as they are cerebrocortical stimulants and overall nervous system excitants; they do not hasten the oxidation of alcohol. The use of hemodialysis should be considered in comatose patients with extremely high blood alcohol concentrations (>500 mg/dL), particularly if accompanied by acidosis, and in those who have concurrently ingested methanol or ethylene glycol or some other dialyzable drug. **Pathologic intoxication** may require the use of restraints and the parenteral administration of diazepam (5 to 10 mg) or haloperidol (2 to 5 mg), repeated once after 30 to 40 min if necessary.

**Methyl, Amyl, and Isopropyl Alcohols and Ethylene Glycol**  
Poisoning with alcohols other than ethyl alcohol is a relatively rare but catastrophic occurrence. **Amyl alcohol** (fusel oil) and **isopropyl alcohol** are used as industrial solvents and in the manufacture of varnishes, lacquers, and pharmaceuticals; in addition, isopropyl alcohol is readily available as a rubbing alcohol. Ingestion of large quantities of any of these agents may follow the ingestion of these alcohols or inhalation of their vapors. The effects of both are much like those of ethyl alcohol, but much more toxic.

**Methyl alcohol** (methanol, wood alcohol) is a component of antifreeze and many combustibles and is used in the manufacture of formaldehyde, as an industrial solvent, and as an adulterant of alcoholic beverages, the latter being the most common source of methyl alcohol intoxication. The oxidation of methyl alcohol to formaldehyde and formic acid proceeds relatively slowly; thus, signs of intoxication do not appear for several hours or may be delayed for a day or longer. Many of the toxic effects are like those of ethyl alcohol, but in addition severe methyl alcohol poisoning may produce serious degrees of acidosis (with an anion gap). The characteristic features of this intoxication, however, are damage to retinal ganglion cells—giving rise to scotomata and varying degrees of blindness, dilated unreactive pupils, and retinal edema—and bilateral degeneration of the putamens, readily visible on computed tomography (CT) scans. Survivors may be left blind or, less often, with putaminal necrosis and dystonia or Parkinsson disease (McLean et al). The most important aspect of treatment is the intravenous administration of large amounts of sodium bicarbonate to reverse acidosis. Medialosis and 4-methylpyrazole (fomepizole), which is a far more effective inhibitor of alcohol dehydrogenase than is alcohol. They recommend this form of treatment for methanol poisoning as well.

Some of the patients who recover from the acute renal and metabolic effects are left with multiple cranial nerve defects, particularly of the seventh and eighth nerves. The latter abnormalities develop 6 to 18 days after the ingestion of ethylene glycol and have been attributed to the deposition of oxalate crystals along the subarachnoid portions of the affected nerves (Spillane et al).

**The Abstinence, or Withdrawal, Syndrome**  
Included under this title is the symptom complex of tremulousness, hallucinations, seizures, confusion, and psychomotor and autonomic overactivity. Although a sustained period of chronic inebriation is the most obvious factor in the causation of these symptoms, they become manifest only after a period of relative or absolute abstinence from alcohol—hence the designation abstinence, or withdrawal, syndrome. This concept is illustrated in Fig. 42-1. Each of the major manifestations of the withdrawal syndrome may occur in more or less pure form and are so described later, but usually they occur in various combinations. Major withdrawal symptoms are observed mainly in the binge, or periodic, drinker, although the steady drinker is not immune if for some reason he stops drinking. The full syndrome, depicted further on, is called delirium tremens.

**Tremulousness and Associated Symptoms**  
The most common single manifestation of the abstinence syndrome is tremulousness, often referred to as “the shakes” or “the jitters,” combined with general irritability and gastrointestinal symptoms, particularly nausea and vomiting. These symptoms first appear after several days of drinking, usually in the morning after a night’s abstinence. The patient “quiets his nerves” with a few drinks and is then able to drink for the rest of the day without undue distress. The symptoms return on successive mornings with increasing severity. The duration of drinking of this type varies greatly. The symptoms then become greatly augmented, reaching their peak intensity 24 to 36 h after the complete cessation of drinking. **Generalized tremor** is the most obvious feature of this illness. It is of fast frequency (6 to 8 Hz), slightly irregular, and variable in severity, tending to diminish when the patient is in quiet surroundings and to increase...
with motor activity or emotional stress. The tremor may be so violent that the patient cannot stand without help, speak clearly, or eat without assistance. Sometimes there is little objective evidence of tremor, and the patient complains only of being “shaky inside.”

Within a few days, flushed facies, anorexia, tachycardia, and tremor characteristic of the early withdrawal syndrome subside to a large extent, but overalertness, tendency to startle easily, and jerkiness of movement may persist for a week or longer. Feelings of uneasiness may not leave the patient completely for 10 to 14 days. According to Porjesz and Begleiter, certain electrophysiologic abnormalities (diminished amplitudes of sensory evoked potentials and prolonged latencies and conduction velocities of auditory brainstem potentials) remain altered long after the clinical abnormalities have subsided.

**Hallucinosis** Symptoms of disordered perception occur in about one-quarter of withdrawing hospitalized tremulous patients. The patient may complain of “bad dreams”—nightmarish episodes associated with disturbed sleep—which he finds difficult to separate from real experience. Sounds and shadows may be misinterpreted, or familiar objects may be distorted and assume unreal forms (illusions). There may also be more overt hallucinations, which are purely visual in type, mixed visual and auditory, tactile, or olfactory, in this order of frequency. There is little evidence to support the popular belief that certain visual hallucinations (bugs, pink elephants) are specific to alcoholism. Actually, the hallucinations comprise the full range of visual experience. They are more often animate than inanimate; persons or animals may appear singly or in panoramas, shrunk or enlarged, natural and pleasant, or distorted, hideous, and frightening. The hallucinosis may be an isolated phenomenon lasting for a few hours, and it may later be attended by other withdrawal signs.

**Acute and Chronic Auditory Hallucinosis** A special type of alcoholic psychosis, consisting of a more or less pure auditory hallucinosis, has been recognized for many years. Kraepelin referred to it as the “hallucinatory insanity of drunkards,” or “alcoholic mania.” A report of 75 such cases was made by Victor and Hope. The central feature of the illness, in the beginning, is the occurrence of auditory hallucinations despite an otherwise clear sensorium during the withdrawal period; i.e., the patients are not disoriented or obtunded, and they have an intact memory. The hallucinations may take the form of unstructured sounds such as buzzing, ringing, gunshots, or clicking (the elementary hallucinations of Bleuler), or they may have a musical quality, like a low-pitched hum or chant. The most common hallucinations, however, are human voices. When the voices can be identified, they are often attributed to the patient’s family, friends, or neighbors—rarely to God, radio, or television. The voices may be addressed directly to the patient, but more frequently they discuss him in the third person. In the majority of cases the voices are maligning, reproachful, or threatening in nature and are disturbing to the patient; a significant proportion, however, are not unpleasant and leave the patient undisturbed. To the patient, the voices are clearly audible and intensely real, and they tend to be exteriorized; i.e., they come from behind a radiator or door, from the corridor, or through a wall, window, or floor. Another feature of auditory hallucinosis (and of visual hallucinosis as well) is that the patient’s response is more or less understandable in light of the hallucinatory content. The patient may call on the police for protection or erect a barricade against invaders; he may even attempt suicide to avoid what the voices threaten. The hallucinations are most prominent during the night, and their duration varies greatly; they may be momentary, or they may recur intermittently for days on end and, in exceptional instances, for weeks or months.

While hallucinating, most patients have no appreciation of the unreality of their hallucinations. With improvement, the patient begins to question the authenticity of his hallucinations and may be reluctant to talk about them and may even question his own sanity. Full recovery is characterized by the realization that the voices were imaginary and by the ability to recall, sometimes with remarkable clarity, some of the abnormal thought content of the psychotic episode.

A unique feature of this alcoholic psychosis is its evolution, in a small proportion of the patients, to a state of *chronic auditory hallucinosis*. The chronic disorder begins like the acute one, but after a short period, perhaps a week or two, the symptomatology begins to change. The patient becomes quiet and resigned, even though the hallucinations remain threatening and derogatory. Ideas of reference and influence and other poorly systematized paranoid delusions become prominent. At this stage the illness may be mistaken for paranoid schizophrenia and indeed was so identified by Bleuler. There are, however, important differences between the two disorders: the alcoholic illness develops in close relation to a drinking bout and the past history rarely reveals schizoid personality traits. Moreover, alcoholic patients with hallucinosis are not distinguished by a high incidence of schizophrenia within their families (Schuckit and Winokur, Scott), and a large number of such patients, whom our colleagues Victor and Adams evaluated long after their acute attacks, did not show signs of schizophrenia. There is some evidence that repeated attacks of acute auditory hallucinosis render the patient more susceptible to the chronic state.

**Withdrawal Seizures** ("Rum Fits") In the setting of alcohol withdrawal either as relative or absolute abstinence following a period of chronic inebriation, convulsive seizures are common. More than 90 percent of withdrawal seizures occur during the 7- to 48-h period following the cessation of drinking, with a peak
incidence between 13 and 24 h. During the period of seizure activity, the electroencephalogram (EEG) is usually abnormal, but it reverts to normal in a matter of days, even though the patient may go on to develop delirium tremens. Also during the period of seizure activity, the patient is unusually sensitive to stroboscopic stimulation; almost half the patients respond with generalized myoclonus or a convulsive seizure (photoparoxysmal response).

Seizures occurring in the abstinence period have a number of other distinctive features. There may be only a single seizure, but in the majority of cases the seizures occur in bursts of two to six over a day, occasionally even more; 2 percent of patients studied by Victor developed status epilepticus. The seizures are grand mal in type, i.e., generalized, tonic-clonic convulsions with loss of consciousness. Focal seizures should always suggest the presence of a focal lesion (most often traumatic) in addition to the effects of alcohol. Twenty-eight percent of Victor’s patients with generalized withdrawal seizures went on to develop delirium tremens (the percentage has been less in other series); almost invariably the seizures preceded the delirium. The postictal confusional state may blend imperceptibly with the onset of the delirium, or the postictal state may have cleared over several hours or even a day or longer before the delirium sets in. Seizures of this type typically occur in patients whose drinking history has extended over a period of many years and must be distinguished from other forms of seizures that have their onset in adult life. It is suggested that the term run fits, or whiskey fits—i.e., the names sometimes used by alcoholics—be reserved for seizures with the attributes described here. This serves to distinguish them from seizures that occur in the interdrinking period, long after withdrawal has been accomplished.

It is important to note that the common idiopathic or posttraumatic forms of epilepsy are also influenced by alcohol. In these types of epilepsy, a seizure or seizures may be precipitated by only a short period of drinking (e.g., a weekend, or even one evening of heavy social drinking); perhaps not surprisingly, in these circumstances, the seizures occur not when the patient is intoxicated but usually the morning after, in the “sobering-up” period. Except for the transient dysrhythmia in the withdrawal period, the incidence of EEG abnormalities in patients who have had run fits is no greater than in normal persons, in sharp contrast to the EEGs of nonalcoholic patients with recurrent seizures.

**Treatment and Prevention of Withdrawal Seizures** Most patients during withdrawal do not require the use of anticonvulsant drugs, since the entire episode of seizure activity—whether a single seizure or a brief flurry of seizures—may have terminated before the patient is brought to medical attention. The parenteral administration of diazepam or sodium phenobarbital early in the withdrawal period had been thought to prevent rum fits in patients with a previous history of this disorder or in those who might be expected to develop seizures on withdrawal of alcohol. This notion has been supported by the observations of D’Onofrio and colleagues that intravenous lorazepam (2 mg in 2 mL of normal saline) was highly effective in preventing recurrent seizures after a first seizure in the same withdrawal period. Only 3 of 100 patients so treated had a second seizure within 48 h compared to 21 of 86 untreated patients. The long-term administration of anticonvulsants is not necessary or practical: if such patients remain abstinent, they will be free of seizures; if they resume drinking, they usually abandon their medications. Furthermore, it is not certain that continued administration of anticonvulsants dependably prevents abstinence seizures. The rare instances of status epilepticus should be managed like status of any other type (page 296). In alcoholics with a history of idiopathic or posttraumatic epilepsy, the goal of treatment should be abstinence from alcohol, because of the tendency of even short periods of drinking to precipitate seizures. Such patients need to be maintained on anticonvulsant drugs.

**Delirium Tremens (“DTs”)** This is the most dramatic and grave of all the alcoholic illnesses. It is characterized by profound confusion, delusions, vivid hallucinations, tremor, agitation, and sleeplessness, as well as by the signs of increased autonomic nervous system overactivity—i.e., dilated pupils, fever, tachycardia, and profuse perspiration. The clinical features of delirium are presented in detail in Chap. 20 as they relate to DTs and to other illnesses that simulate it.

Delirium tremens develops in one of several settings. The patient, an excessive and steady drinker for many years, may have been admitted to the hospital for an unrelated illness, accident, or operation and, after 2 to 4 days, occasionally even later, becomes delirious. Or, following a prolonged drinking binge, the patient may have experienced several days of tremulousness and hallucinosis or one or more seizures and may even be recovering from these symptoms when delirium tremens develops, rather abruptly as a rule.

As to the frequency of delirium tremens, Foy and Kay reported an incidence of 0.65 percent of all patients admitted for other reasons to a large general hospital. Among 200 consecutive alcoholics admitted to a city hospital, Ferguson et al reported that 24 percent developed delirium tremens; of these, 8 percent died—figures that are considerably higher than those recorded in our hospitals. Of course, the reported incidence of delirium tremens will vary greatly, depending on the population served by a particular hospital.

In the majority of cases delirium tremens is benign and short-lived, ending as abruptly as it begins. Consumed by relentless activity and wakefulness for several days, the patient falls into a deep sleep and then awakens lucid, quiet, and exhausted, with virtually no memory of the events of the delirious period. Somewhat less commonly, the delirious state subsides gradually with intermittent episodes of recurrence. In either event, when delirium tremens occurs as a single episode, the duration is 72 h or less in over 80 percent of cases. Less frequently still, there may be one or more relapses, several episodes of delirium of varying severity being separated by intervals of relative lucidity—the entire process lasting for several days or occasionally for as long as 4 to 5 weeks.

In the past, approximately 15 percent of cases of delirium tremens ended fatally, but the figure now is closer to 5 percent. In many of the fatal cases there is an associated infectious illness or injury, but in others no complicating illness is discernible. Many of the patients die in a state of hyperthermia; in some, death comes so suddenly that the nature of the terminal events cannot be determined. Reports of a negligible mortality rate in delirium tremens can usually be traced to a failure to distinguish between delirium tremens and the minor forms of the withdrawal syndrome, which are far more common and practically never fatal.

We make note here of our experience with delirium following the withdrawal of barbiturates, which is almost identical to the DTs, including the abrupt cessation of symptoms, as discussed on page 1022.

There are also alcohol withdrawal states, closely related to delirium tremens and about as frequent, in which one facet of the delirium tremens complex assumes prominence, to the virtual exclusion of the other symptoms. The patient may simply exhibit a transient state of quiet confusion, agitation, or peculiar behavior lasting several days or weeks. Or there may be a vivid hallucina-
nergic system is also inhibited by alcohol. Evaluation is not nearly so simple, insofar as the excitatory glutamatergic neurotransmitter are downregulated by chronic alcohol use, but the situation has been mentioned earlier. The GABA-nergic system has been most conspicuous in the genesis of alcohol tolerance and withdrawal have associated with hyperexcitability of the nervous system, is responsible for associated injuries (particularly head injury with cerebral lacerations or subdural hematoma), infections (pneumonia or meningitis), pancreatitis, and liver disease. Because of the frequency and seriousness of these complications, chest films and a CT scan should be obtained in most instances, and lumbar puncture should be performed if there is suspicion of meningitis. In severe forms of delirium tremens, the temperature, pulse, and blood pressure should be measured at frequent intervals in anticipation of peripheral circulatory collapse and hyperthermia, which, added to the effects of injury and infection, are the usual causes of death in this disease. In the case of hypotension, one must act quickly, utilizing intravenous fluids and, if called for, vasopressor drugs. The occurrence of hyperthermia demands the use of a cooling mattress or evaporative cooling in addition to specific treatment for any infection that may be present.

An additional important element in treatment is the correction of fluid and electrolyte imbalance, particularly hypokalemia and severe hypomagnesemia. Severe degrees of agitation and perspiration may require the administration of up to 5 L of fluid daily, of which at least 1500 to 2000 mL should be normal saline. The specific electrolytes and the amounts that must be administered are governed by the laboratory values for these electrolytes. If the serum sodium is extremely low, one must be cautious in raising the level lest a central pontine myelolysis be induced (see page 973). In the rare case of hypoglycemia, the administration of glucose is an urgent matter. Patients who present with severe alcoholic ketoacidosis and normal or only slightly elevated blood glucose concentrations usually recover promptly, without the use of insulin.

It must be emphasized that a special danger attends the use of glucose solutions in alcoholic patients. The administration of intravenous glucose may serve to consume the last available reserves of thiamine and precipitate Wernicke disease, as discussed in Chap. 41. Typically, these patients have subsisted on a diet disproportionately high in carbohydrate (in addition to alcohol, which is metabolized entirely as carbohydrate) and low in thiamine, and their body stores of B vitamins may have been further reduced by gastroenteritis and diarrhea. For this reason it is good practice to add B vitamins, specifically thiamine (which may also be supplemented by intramuscular injection), in all cases requiring parenterally administered glucose—even though the alcoholic disorder under treatment, e.g., delirium tremens, is not primarily due to vitamin deficiency.

With respect to the use of medications, it is important to distinguish between mild withdrawal symptoms, which are essentially benign and responsive to practically any sedative drug, and full-blown delirium tremens. There is no certain way to predict whether a patient with the early signs of withdrawal will progress to a state of delirium tremens. In the latter state, the object of drug therapy is to blunt the psychomotor overactivity, prevent exhaustion, and facilitate the administration of parenteral fluid and nursing care; one should not attempt to suppress agitation at all costs, since doing so requires an amount of drug that might seriously depress respiration.

A wide variety of drugs are effective in controlling withdrawal symptoms. The more popular ones have been chlor Diazepam (Librium), diazepam (Valium), meprobamate, hydroxyzine (Vis-taril) and the ancillary medications, clonidine and beta-adrenergic...
blockers, and both older and newer anticonvulsant drugs such as gabapentin, which may reduce the requirement for sedative drugs. There is little to choose among the primary drugs in respect to their therapeutic efficacy. More importantly, there are few data to indicate that any one of them can prevent hallucinosis or delirium tremens or shorten the duration or alter the mortality rate of the latter disorder (Kaim et al). In general, phenothiazine drugs should be avoided because they reduce the threshold to seizures. Probably, the use of any of the diazepine medications is as effective as a single dose of lorazepam in prophylactically suppressing seizures (see earlier discussion).

If parenteral medication is necessary, we prefer 10 mg of diazepam or chlordiazepoxide given intravenously and repeated once or twice at 20- to 30-min intervals until the patient is calm but awake; we have also favored midazolam in closely controlled circumstances. Beta-blocking agents, such as propranolol and atenolol, are helpful in reducing heart rate, blood pressure, and the tremor to some extent. Lofexidine, an alpha_2 agonist that blocks autonomic outflow centrally, and clonidine are similarly effective in reducing the severity of most of the withdrawal symptoms, but they are not recommended as the sole treatments. Corticosteroids have no place in the treatment of the withdrawal syndrome.

**Nutritional Diseases of the Nervous System**
(See Chap. 41)

Alcoholism provides the ideal setting for the development of nutritional diseases of the nervous system. Although only a small proportion of alcoholics develop nutritional diseases, the overall number of these diseases is substantial because of the frequency of alcoholism. The importance of the alcohol-induced deficiency diseases relates to the fact that they are preventable and, if neglected, may lead to permanent disability. These illnesses are discussed fully in the preceding chapter, "Diseases of the Nervous System Due to Nutritional Deficiency."

**Disorders of Uncertain Pathogenesis Associated with Alcoholism**

Also discussed in Chap. 41 are so-called alcoholic cerebellar degeneration and Marchiafava-Bignami disease. The former is almost certainly of nutritional origin; in the latter a nutritional-metabolic etiology seems likely but has not been established. Central pontine myelinolysis, though frequently observed in alcoholics, is more appropriately considered with the acquired metabolic disorders (Chap. 40). Certain disorders of skeletal and cardiac muscle associated with alcoholism (acute alcoholic myopathy and cardiomyopathy) are described in Chap. 51, with the myopathies due to drugs and toxins. There remain to be discussed several diverse disorders that have been attributed to alcoholism but whose causal relationship to alcohol abuse, nutritional deficiency, or some other factor is not clear.

**Alcoholic Dementia and Cerebral Atrophy**
The term alcoholic dementia is used widely and often indiscriminately to designate a presumptively distinctive form of dementia that is attributable to the chronic, direct effects of alcohol on the brain. Unfortunately, a syndrome subsumed under the title of alcoholic dementia and its many synonyms that appear in the older literature (alcoholic deteriorated state, chronic alcoholic psychosis, chronic or organic brain syndrome due to alcohol) has never been delineated satisfactorily, either clinically or pathologically. In the *Comprehensive Textbook of Psychiatry*, it has been defined as "a gradual disintegration of personality structure, with emotional lability, loss of control, and dementia" (Sadock and Sadock). Purported examples of this state show a remarkably diverse group of symptoms, including jealousy and suspiciousness; coarsening of moral fiber and other personality and behavioral disorders; deterioration of work performance, personal care, and living habits; and disorientation, impaired judgment, and defects of intellectual function, particularly of memory.

In recent years, there have been attempts to redefine alcoholic dementia. Cutting and also Lishman have expressed the view that the term Korsakoff psychosis should be limited to patients with a fairly pure disorder of memory of acute onset and that patients with more global symptoms of intellectual deterioration, of gradual evolution, be considered to have alcoholic dementia. These are rather weak diagnostic criteria. As pointed out in Chap. 41, Korsakoff psychosis may have an insidious onset and gradual progression, and patients with this disorder, in addition to an amnesic defect, characteristically show disturbances of cognitive functions that depend little or not at all on memory. More importantly, in none of the patients designated by these authors as having alcoholic dementia was there a neuropathologic examination, without which the clinical assessment must remain arbitrary and imprecise.

The pathologic changes that purportedly underlie primary alcoholic dementia are even less precisely defined than the clinical syndrome. Courville, whose writings have been quoted most frequently in this respect, described a series of cerebral cortical changes that he attributed to the toxic effects of alcohol. Some of them turn out on close inspection to be quite nonspecific, reflecting nothing more than the effects of aging or the insignificant artifacts of tissue fixation and staining. More recently, Harper and colleagues have reported that the mean brain weight is decreased in alcoholics and the pericerebral space is increased in volume—findings that do no more than confirm the brain shrinkage that is demonstrable by CT scans in many alcoholics and is to some extent reversible with sustained abstinence (see later). Also, using an automated cell-counting method, these authors reported a reduction in the number of neurons in the superior frontal cortex. Other investigators, using more accurate (stereologic) counting methods, have not duplicated these findings (Hansen et al; Jensen and Pakenberg), nor have experimental studies in animals settled the problem.

In our experience, the majority of cases that come to autopsy with the label of alcoholic dementia prove simply to have the lesions of the Wernicke-Korsakoff syndrome. Traumatic lesions of varying degrees of severity are commonly added. Other cases show the lesions of Marchiafava-Bignami disease, hepatic encephalopathy, or an unrelated communicating hydrocephalus, Alzheimer disease, ischemic necrosis, or some other disease quite unrelated to alcoholism. Practically always in our material, the clinical stage can be accounted for by one or a combination of these disease processes, and there has been no need to invoke a hypothetical toxic effect of alcohol on the brain. This has also been the experience of Torvik and associates; with a few exceptions, such as coincidental Alzheimer disease, all their cases that had been diagnosed as having alcoholic dementia turned out, on neuropathologic examination, to have the chronic lesions of Wernicke-Korsakoff disease.

In brief, the most serious flaw in the concept of a primary alcoholic dementia is that it lacks a distinctive, well-defined pathology. Until such time as the morphologic basis is established,
its status must remain ambiguous. A more detailed discussion of this subject and of so-called alcoholic cerebral atrophy (see later) can be found in the review by Victor (1994), listed in the References.

Cerebral atrophy, like the "alcoholic deteriorated state," does not constitute a well-defined entity. The concept of alcoholic cerebral atrophy was the product originally of pneumoencephalographic studies. RELATIVELY young alcoholics, some with and some without symptoms of cerebral disease, were often found to have enlarged cerebral ventricles and widened sulci, mainly of the frontal lobes (see, for example, reports of Brewer and Perrett and of Haug). Similar findings have been reported in chronic alcoholics examined by CT scanning and MRI (see review by Carlen et al).

The clinical correlates of these radiologic findings are quite unclear. Most often, the finding of large ventricles comes as a surprise, no symptoms or signs of neuropsychiatric disease having been noted in the course of the usual neurologic testing. In this connection, the findings of Wilkinson are of particular importance. He demonstrated that in clinically normal alcoholics, the radiologic measures of "brain atrophy" were age-related; once the age factor was removed, the CT findings in these subjects did not differ significantly from those in nonalcoholic controls.

The term alcoholic cerebral atrophy implies that chronic exposure of the brain to alcohol causes an irreversible loss of cerebral tissue. From the study by Harper and colleagues this may indeed be true, but it requires confirmation. The idea of alcoholic atrophy is open to criticism mainly on the grounds that dilated ventricles have in fact been reversible to a considerable extent when abstinence is maintained (Carlen et al, Lishman, Zipursky et al, Schroth et al). Until this matter has been studied further, it would be preferable to refer to this condition as an asymptomatic ventricular enlargement and sulcal widening in alcoholics, rather than as cerebral atrophy.

Fetal Alcohol Syndrome

That parental alcoholism may have an adverse effect on the offspring has been a recurrent theme in medical writings. Probably the first allusion to such a relationship was that of Sullivan (1899), who reported that the mortality among the children of drunken mothers was more than two times greater than that among children of nondrinking women of "similar stock." This increased mortality was attributed by Sullivan and later by Haggard and Jellinek to postnatal influences such as poor nutrition and a chaotic home environment rather than to the intrauterine effects of alcohol. The idea that maternal alcoholism could damage the fetus was generally rejected and relegated to the category of superstitions about alcoholism or the claims of temperance ideologues.

In the late 1960s, the effects of alcohol abuse on the fetus were rediscovered, so to speak. Lemoine and associates in France and then Ulleland and Jones and Smith in the United States described a distinctive pattern of abnormalities in infants born of severely alcoholic mothers. They stated that the affected infants are small in length in comparison to weight, and most of them fall below the third percentile for head circumference. They are distinctly small in length in comparison to weight, and most of them fall below the third percentile for head circumference. The physical stigmata of the syndrome become less distinctive after puberty, but practically all adolescents are left with some degree of mental retardation and behavioral abnormalities.

The pathologic changes that underlie the FAS have been studied in a small number of cases and no uniform change has emerged. Of some interest are observations such as those of Ikonomidou and coworkers that demonstrate a profound effect of alcohol exposure on the deletion of millions of neurons in the developing rat brain by a mechanism of apoptosis. The main vulnerability occurs during periods of synaptogenesis, which in humans extends from the sixth month of gestation onward.

It is noteworthy that infants born to nonalcoholic mothers who had been subjected to severe dietary deprivation during pregnancy (during World War II) were small and often premature, but these infants did not show the pattern of malformations that characterizes FAS. Alcohol readily crosses the placenta in humans and animals; in the mouse, rat, chick, miniature swine, and beagle dog, alcohol has been shown to have both embryotoxic and teratogenic effects. Thus, the evidence to date favors a toxic effect of alcohol, although a possible toxic effect of acetaldehyde and smoking and a possible contributory role for nutritional deficiency have not been totally excluded.

Unequivocal cases of FAS observed to date have occurred only in infants born to severely alcoholic mothers (many of them with delirium tremens and liver disease) who continued to drink heavily throughout pregnancy. It is important to state that a relationship to lesser degrees of alcohol intake is far less secure. Data derived from the collaborative study sponsored by the National Institutes of Health indicate that about one-third of the offspring of women who are heavy drinkers have the FAS. Abel and Sokol have estimated that the worldwide incidence of the FAS is 1.9 per 1000 live births and have pronounced it to be the leading known cause of mental retardation in the western world. The degree of maternal alcoholism that is necessary to produce the syndrome and the critical stage in gestation during which it occurs are still vague. The various teratogenic effects described earlier are estimated to occur in the embryonic period, i.e., in the first 2 months of fetal life. Other non-teratogenic effects appear to be related to periods during gestation when the fetus is exposed to particularly high alcohol levels.
A comprehensive account of alcohol-related birth defects and the controversial issues surrounding this subject is contained in a special issue of *Alcohol Health and Research World*, published by the National Institutes of Health (Vol. 18, 1994).

**Neurologic Complications of Alcoholic Cirrhosis and Portal-Systemic Shunts**

This category of alcoholic disease is discussed in Chap. 40, in connection with the acquired metabolic disorders of the nervous system.

**Treatment of Alcohol Addiction**

Following recovery from the acute medical and neurologic complications of alcoholism, the patient still must face the underlying problem of alcohol dependence. To treat only the medical complications and leave the management of the drinking problem to the patient alone is shortsighted. Almost always, drinking is resumed, with a predictable recurrence of medical illness. For this reason the physician must be prepared to deal with the addiction or at least to initiate treatment.

The problem of excessive drinking is formidable but not nearly as hopeless as it is generally made out to be (see review of O’Connor and Schottenfeld). A common misconception among physicians is that specialized training in psychiatry and an inordinately large amount of time are required to deal with the addictive drinker. Actually, a successful program of treatment can be initiated by any interested physician, using the standard techniques of history taking, establishing rapport with the patient, and setting up a schedule of frequent visits, though not necessarily for prolonged periods. Our position on this matter was reinforced by a controlled study of problem drinkers in whom treatment was equally successful whether carried out by general practitioners or by specialists (Drummond et al). The various approaches to the patient who has a drinking problem but is not yet alcohol dependent are summarized by O’Connor and Schottenfeld. They favor brief and focused interventions that point out the problem in unambiguous terms and offer empathetic advice; the physician is often the central person in this interaction.

The requisite for successful treatment is total abstinence from alcohol; for all practical purposes, this represents the only permanent solution. It is generally agreed that any attempts to curb the drinking habit will fail if the patient continues to drink. There are said to be alcohol addicts who have been able to reduce their intake of alcohol and eventually to drink in moderation, but they must represent only a small proportion of the addicted population. Alcoholic patients must be made fully aware of the medical and social consequences of continued drinking. They must also be made to understand that because of some constitutional peculiarity (like that of the diabetic, who cannot handle sugar) they are incapable of drinking in moderation. These facts should be presented in much the same way as one would explain the essential features of any other disease; there is nothing to be gained from adopting a punitive or moralizing attitude. Yet patients should not be given the idea that they are in no way to blame for their illness; there appears to be an advantage in making them feel that they are responsible for doing something about their drinking.

A number of methods have proved valuable in the short- and long-term management of alcoholic patients. The more important of these are admission to a detoxification or special hospital unit, rehabilitative therapy, aversion treatment, the use of disulfiram (Antabuse), and the participation in self-help organizations for recovery from alcoholism. Detoxification clinics and special hospital units for the treatment of alcoholism are now widely available. The physician should be fully aware of all the community resources available for the management of this problem and should be prepared to take advantage of them in appropriate cases. Most inpatient programs include individual and group counseling, didactics about the illness and recovery, and family intervention. Outpatient treatment (of individuals or groups) is widely available, either from specialized facilities or from specialized therapists in general mental health facilities; family counseling is usually offered as well and is often beneficial. Most professional alcoholism treatment in the United States includes an introduction to the methods and utilization of Alcoholics Anonymous (AA, see later).

Disulfiram interferes with the metabolism of alcohol, so that a patient who takes both alcohol and disulfiram accumulates an inordinate amount of acetaldehyde in the tissues, resulting in nausea, vomiting, and hypotension, sometimes pronounced in degree. It is no longer considered necessary to demonstrate these effects to patients; it is sufficient to warn them of the severe reactions that may result if they drink while they have the drug in their bodies. Treatment with disulfiram is instituted only after the patient has been sober for several days, preferably longer. It should never be given to patients with cardiac or advanced liver disease. Should the patient drink while taking disulfiram, the ensuing reaction is usually severe enough to require medical attention, and a protracted spree can thus be prevented. Disulfiram may cause a polyneuropathy if continued over months or years, but this is a rare complication.

Several other drugs have recently become popular in maintaining abstinence. The opioid antagonist naltrexone (50 mg/day) has been used for this purpose, with mixed but overall favorable results. In Europe, a modicum of success has been achieved with the GABA and glutamate modulator acamprosate (2000 mg daily), but this drug is not yet available in the United States. Putatively, a novel approach has been to block the addicting effects of alcohol on the mesolimbic dopaminergic system by the use of anticonvulsants such as topiramate. Johnson and colleagues were able to demonstrate a reduction in alcoholic intake in patients taking this drug, in comparison to placebo, albeit over only a 12-week period. The use of these medications and the possible reasons for conflicting results between studies are given in a thorough review by Swift.

Alcoholics Anonymous, an informal fellowship of recovering alcoholics, has proved to be the single most effective force in the rehabilitation of alcoholic patients. The philosophy of this organization is embodied in its “12 Steps,” a series of principles for sober living that guide the patient to recovery. The AA philosophy stresses in particular the practice of making restitution, the necessity to help other alcoholics, trust in a higher power, the group confessional, and the belief that the alcoholic alone is powerless over alcohol. Although accurate statistics are lacking, it is said that about one-third of the members who express more than a passing interest in the program attain a state of long-sustained or permanent sobriety. The methods used by AA are not acceptable to every patient, but most who persist in its activities appear to benefit; in particular, the physician should not accept a patient’s initial negative reaction as reason to abandon AA as a mode of treatment.

Finally, it should be noted that alcoholism is frequently associated with psychiatric disease of other types, particularly socio-
pathy and affective illness (the term “dual diagnosis” is used by psychiatrists to denote this combination of psychopathologies). In the latter case, the prevailing mood is far more often one of depression than of mania and is more often encountered in women, who are more apt to drink under these conditions than are men. In these circumstances, expert psychiatric help should be sought, preferably from someone who is also familiar with addictive diseases.

The role of physicians in caring for patients with alcohol problems has been outlined by several governmental agencies and are summarized in the review article by O’Connor and Schottenfeld.

CHAPTER 43

DISORDERS OF THE NERVOUS SYSTEM DUE TO DRUGS, TOXINS, AND OTHER CHEMICAL AGENTS

Subsumed under this title is a diverse group of disorders of the nervous system that result from the introduction into the body of drugs and other injurious or poisonous substances. A drug can be broadly defined as any chemical agent that affects living processes, but for purposes of this chapter, the discussion is limited to such drugs in modern use for the prevention and treatment of diseases. In addition, the neurologist must be concerned with the myriad of chemical agents that have no therapeutic utility but may adversely affect the nervous system; they abound in the environment as household products, insecticides, industrial solvents, and other poisons, the toxic neurological effects of which must be recognized and treated. Also included among neurotoxins are those generated by bacteria and other infectious agents, as well as several found in nature, such as marine toxins and agents elaborated by living animals. These are designated as endogenous if they arise within the body and exogenous if introduced from outside. Such a division cannot always be sharply drawn, as in the case of toxins produced by certain bacteria after being introduced from the outside (e.g., tetanus).

It would hardly be possible within the confines of this chapter to discuss with any degree of completeness the innumerable drugs and toxins that affect the nervous system. The interested reader is referred to a number of comprehensive monographs and references listed at the end of this chapter. In addition, an up-to-date handbook of pharmacology and toxicology should be part of the library of every physician.

The scope of this chapter is also limited because the therapeutic and adverse effects of many drugs are considered elsewhere in this volume in relation to particular symptoms and diseases. Thus, the toxic effects of ethyl, methyl, amyl, and isopropyl alcohol, as well as ethylene and diethylene glycol, are discussed in Chap. 42, on alcohol. The adverse effects of antibiotics on cochlear and vestibular function and on neuromuscular transmission are discussed in Chaps. 15 and 53, respectively. Many of the undesirable side effects of the common drugs used in the treatment of extrapyramidal motor symptoms, pain, headache, convulsive seizures, sleep disorders, psychiatric illnesses, and so forth are also considered in the chapters dealing with each of these disorders and in the chapters that cover psychiatric diseases. Cyanide and carbon monoxide poisoning are discussed in relation to anoxic encephalopathy (Chap. 40). A number of therapeutic agents that damage the peripheral nerves (e.g., cisplatin, disulfiram, vincristine, dapsone, etc.) are mentioned in this chapter but are discussed further in Chap. 46 on peripheral neuropathy, and those affecting muscle, in Chap. 51.

Of necessity, the presentation of this subject must be introduced by some general remarks on the action of drugs on the nervous system and on the selective ways in which the more common categories of drugs and chemical agents affect the nervous system. The references at the end of the chapter are listed in relation to each of these categories:

1. The general principles guiding the action of drugs on the nervous system
2. The addicting drugs: opiates and synthetic analgesics
3. Sedative-hypnotic drugs
4. Antipsychotic drugs
5. Antidepressant drugs
6. Stimulants
7. Psychoactive drugs
8. Bacterial toxins
9. Plant poisons, venoms, bites, and stings
10. Heavy metals
11. Industrial toxins
12. Antineoplastic and immunosuppressive agents
13. Antibiotics of various classes
14. Cardioactive agents (beta blockers, digitalis derivatives, amiodarone)

NEUROPHARMACOLOGY: GENERAL PRINCIPLES

Of primary importance is the manner in which a therapeutic agent, specifically its chemical structure, affects the biochemistry and physiology of neurons and their supporting elements (pharmacodynamics). The rational use of any drug requires a knowledge of the best route of administration, the drug’s absorption characteristics, its distribution in the nervous system and other organs, and its biotransformations and excretion (pharmacokinetics). Since every drug, if given in excess, has some adverse effects, therapeutics and toxicology are inseparable.

Drug–Nervous System Interactions

In no other field of neurology is it more apparent that all systems of neurons are not identical. Each has its own vulnerabilities to particular drugs and toxic agents. This principle, originally enunciated by O. and C. Vogt in their theory termed pathoclisis, has been elegantly confirmed by tracing chemical molecules to specific aggregates of neurons. Thus, pathoclisis explains the preferential effects of anesthetics on the neurons of the upper brainstem reticular formation, which, with its diffuse cortical connections, underlies consciousness. There are examples not only of certain groups of nerve cells being selectively destroyed by a particular agent but also of their function and particular parts of their structure being altered. Drugs may actually be targeted even to the terminal axons, dendrites, neurofilaments, or receptors on pre- and postsynaptic surfaces of neurons or to certain of their metabolic activities,
whereby they synthesize and release neurotransmitters or maintain their cellular integrity by the synthesis of ribonucleic acid (RNA), deoxyribonucleic acid (DNA), and other proteins. The production of parkinsonism by the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is an excellent example of pathosis, in which a disease process and a synthetic toxin effect a progressive loss of melanin-bearing nigral neurons and a depletion of their neurotransmitter, dopamine. An intriguing but not yet fully established extension of this pathosis relates to the manner in which certain toxins affect only individuals with a genetic disposition to a degenerative neurologic disease.

Evidence is also accumulating regarding the mechanisms by which drugs and toxins can act on particular steps in the formation, storage in presynaptic vesicles, release, uptake, catabolism, and resynthesis of neurotransmitters such as dopamine, serotonin, noradrenaline, acetylcholine, and other catecholamines. Johnston and Silverstein have summarized current views of how these transmitters and modulating agents, by attaching to receptors at neuronal synapses, are able to increase or decrease the permeability of ion channels and stimulate or inhibit second cytoplasmic messengers. Many examples can be given. Drugs such as L-dopa, tryptophan, and choline enhance the synthesis of dopamine, serotonin, and acetylcholine, respectively. Baclofen modulates the release of gamma-aminobutyric acid (GABA), the main inhibitory transmitter in the central nervous system (CNS). Bretyllium prevents the release of norepinephrine; butulinum toxin has a similar effect on acetylcholine in the neuromuscular junction, and tetanus toxin on GABA in Renshaw cells of the spinal cord. Amantadine, an antiviral agent, is thought to promote the release of dopamine, guanidine, and acetylcholine. Benzodiazepines, bromocriptine, and methylphenidate are viewed as receptor agonists; the phenothiazines and anticholinergics act as receptor antagonists. Certain drugs enhance the activity of neurotransmitters by inhibiting their reuptake, as, for example, the class of antidepressant drugs that has a relatively selective influence on the reuptake of serotonin. One must not assume that these are the exclusive modes of action of each of these drugs, but these data are instructive and indicate the future direction of neuropharmacology.

Lacking still is information about the precise mechanisms of even the most common inhalational anesthetics. It has been assumed that by their lipid solubility they alter the physicochemical properties of the cell membrane and thus impair the activities of the membrane receptor systems that regulate ion channels, particularly the chloride and calcium channels. A discussion of the clinical effects of general anesthesia can be found on page 309.

Bioavailability

A majority of drugs that act on the nervous system are ingested; factors that govern their intestinal absorption must, therefore, be taken into account. Small molecules usually enter the plasma by diffusion, larger ones by pinocytosis. The substances with which the drugs are mixed (excipients); the presence of food, other drugs, or intestinal diseases; and the age of the patient all influence the rate of absorption and blood concentrations. Different calculations are necessary for intramuscular, subcutaneous, and intrathecal routes of administration. To some extent, the solubilities of drugs (in lipid or water) determine the routes by which they can be given; some drugs, such as morphine, can be administered by manifold routes. Carried in the blood, the drug (or toxin) reaches many tissues, including the nervous system; protein binding in the plasma has an important influence on distribution. Many drugs and toxic substances bind to serum albumin and other serum proteins, limiting the availability of the ionized form. The common drug and toxin transformations involve hydroxylation, deamination, oxidation, and dealkylation, which enhance their solubility and elimination by the kidney. Most of these catalytic processes occur in liver cells and utilize multiple enzymes.

To enter the extracellular compartment of the nervous system, a drug or toxic agent must transgress the tight capillary endothelial barrier (blood-brain barrier) and the barrier between the blood and cerebrospinal fluid (blood-CSF barrier). Intrathecal injection circumvents these barriers, but then the agent tends to concentrate in the immediate subpial and subependymal regions. The process of movement from plasma to brain is by diffusion through capillaries or by facilitated transport. The solubility characteristics of the drug determine its rate of diffusion.

In the following discussion on neurotoxins, the reader will appreciate a number of novel phenomena: tolerance (lessening effect of increasing dose), dependence and addiction (insatiable need), habituation, drug-seeking behaviors, and abstinence with its associated withdrawal effects. These were described in Chap. 42 on alcoholism and are further elaborated in sections below. Particularly difficult in reference to drugs such as nicotine is the separation of habituation from addiction, i.e., of psychologic dependence from physical dependence (see further on).

To make intelligent use of the pharmacologic agents described later, the neurologist must know about their pharmacodynamic and pharmacokinetic properties. The few examples given earlier are intended to provide a glimpse of the complex interactions between chemical agents and the cells of the nervous system. For more specific information, the reader is referred to The Biochemical Basis of Neuropharmacology by Cooper, Bloom, and Roth, an excellent text that we have consulted through its many editions and to Goodman and Gilman’s The Pharmacological Basis of Therapeutics, now in its tenth edition, edited by Hardman and colleagues. The continued elucidation of the modes of action of the several hundred drugs and toxins that act on the nervous system promises to yield important information about the biochemical physiology of neurons and opens for study an inviting field of experimental neuropharmacology and neuropathology.

OPIATES AND SYNTHETIC ANALGESIC DRUGS

The opiates, strictly speaking, include all the naturally occurring alkaloids in opium, which is prepared from the seed capsules of the poppy Papaver somniferum. For clinical purposes, the term opiate refers only to the alkaloids that have a high degree of analgesic activity, i.e., morphine and codeine. The terms opioid and narcotic-analgesic designate drugs with actions similar to those of morphine. Compounds that are chemical modifications of morphine include diacetylmorphine, or heroin (still the most commonly abused opioid), hydromorphone (Dilaudid), codeine, hydrocodone, oxy-morphine, and oxycodone (Percodan, OxyContin). A second class of opioids comprises the purely synthetic analogs: meperidine (Demerol) and its congeners, notably fentanyl (Sublimaze), methadone (Dolophine), levophanol (Levo-Dromoran), propoxyphene (Darvon), pentazocine (Talwin), diphenoxylate (the main component of Lomotil), and phenoxyzine (Prinadol). The synthetic analogs are similar to the opiates, in both their pharmacologic effects and patterns of abuse, the differences being mainly quantitative.
The clinical effects of the opioids are considered from two points of view: (1) acute poisoning and (2) addiction.

Opioid Overdose

Because of the common and particularly the illicit use of opioids, poisoning is a frequent occurrence. This happens also as a result of ingestion or injection with suicidal intent, errors in the calculation of dosage, the use of a substitute or contaminated street product, or unusual sensitivity. Children exhibit an increased susceptibility to opioids, so that relatively small doses may prove toxic. This is true also of adults with myxedema, Addison disease, chronic liver disease, and pneumonia. Acute poisoning may also occur in addicts who are unaware that available opioids vary greatly in potency and that tolerance for opioids declines quickly after the withdrawal of the drug; upon resumption of the habit, a formerly well-tolerated dose can be fatal.

Varying degrees of unresponsiveness, shallow respirations, slow respiratory rate (e.g., two to four per minute) or periodic breathing, pinpoint pupils, bradycardia, and hypothermia are the well-recognized clinical manifestations of acute opioid poisoning. In the most advanced stage, the pupils dilate, the skin and mucous membranes become cyanotic, and the circulation fails. The immediate cause of death is usually respiratory depression, with consequent asphyxia. Patients who suffer a cardiopulmonary arrest are sometimes left with all the known residua of anoxic encephalopathy. Mild degrees of intoxication are revealed by anorexia, nausea, vomiting, constipation, and loss of sexual interest.

Treatment of Overdose

This consists of the administration of naloxone (Narcan), or the longer acting nalmefene, both specific antidotes to the opiates and also to the synthetic analgesics. The dose of naloxone is 0.7 mg/70 kg body weight intravenously, repeated if necessary once or twice at 5-min intervals. In cases of opioid poisoning, the improvements in circulation and respiration and reversal of miosis are usually dramatic. In fact, failure of naloxone to produce such a response should cast doubt on the diagnosis of opioid intoxication. If an adequate respiratory and pupillary response to naloxone is obtained, the patient should nonetheless be observed for up to 24 h and further doses of naloxone (50 percent higher than the ones previously found effective) can be given intramuscularly as often as necessary. Naloxone has less direct effect on consciousness, however, and the patient may remain drowsy for many hours. This is not harmful provided respiration is well maintained. Although nalmefene has a plasma half-life of 11 h, compared to 60-90 min for naloxone, it has no clear advantage in emergency practice. Gastric lavage is a useful measure if the drug was taken orally. This procedure may be efficacious many hours after ingestion, since one of the toxic effects of opioids is pylorospasm and ileus, which causes much of the drug to be retained in the stomach.

Once the patient regains consciousness, complaints such as pruritus, sneezing, tearing, piloerection, diffuse body pains, yawning, and diarrhea may appear. These are the recognizable symptoms of the opioid abstinence, or withdrawal, syndrome, described later. An antidote therefore must be used with great caution in an addict who has taken an overdose of opioid, because in this circumstance it may precipitate withdrawal phenomena. Nausea and severe abdominal pain, due presumably to pancreatitis (from spasm of the sphincter of Oddi), are other troublesome symptoms of opiate use or withdrawal. Seizures are rare.

Opioid Addiction

Just 50 years ago there were an estimated 60,000 persons addicted to narcotic drugs in the United States, exclusive of those who were receiving drugs because of incurable painful diseases. This represented a relatively small public health problem in comparison with the abuse of alcohol and barbiturates. Moreover, opioid addiction was of serious proportions in only a few cities—New York, Chicago, Los Angeles, Washington, and Detroit. Since the late 1960s, a remarkable increase in opioid (mainly heroin) addiction has taken place. The precise number of opioid addicts is not known but is currently estimated by the Drug Enforcement Administration to be well more than 500,000 (a disproportionate number in New York and a few other large cities). The problem assumes enormous importance when one recognizes that one-quarter of addicts are seropositive for human immunodeficiency virus (HIV) and are the chief source of transmission of AIDS to newborns and to the heterosexual nonaddicted population. The prevalence and patterns of opioid abuse have been reviewed by Brust.

Etiology and Pathogenesis

A number of factors—socioeconomic, psychologic, and pharmacologic—contribute to the genesis of opioid addiction. In our culture, the most susceptible subjects are young men or delinquent youths living in the economically depressed areas of large cities, but significant numbers are now found in suburbs and in small cities as well. The onset of opioid use is usually in adolescence, with a peak at 17 to 18 years; fully two-thirds of addicts start using the drugs before the age of 21. Almost 90 percent of addicts engage in criminal activity, often to obtain their daily ration of drugs, but most of them have a history of arrests or convictions antedating their addiction. Also, many of them have psychiatric disturbances, conduct disorder and sociopathy being the most common (“dual-diagnosis,” in psychiatric jargon). Monroe and colleagues, using the Lexington Personality Inventory, examined a group of 837 opioid addicts and found evidence of antisocial personality in 42 percent, emotional disturbance in 29 percent, and thinking disorder in 22 percent; only 7 percent were free of such disorders. Obviously, vulnerability to addiction is not confined to one personality type.

Association with addicts is the apparent explanation for beginning addiction. One addict recruits another person into addiction, and the new recruit does likewise. In this sense opioid addiction is contagious, and partly as a result of this pattern, heroin addiction has attained epidemic proportions. A small, almost insignificant proportion of addicts are introduced to drugs by physicians in the course of an illness. Therefore, there has been a regrettable tendency not to prescribe opiates to patients with acute or chronic pain (e.g., cancer pain) because of the risk of addiction.

Opioid addiction consists of three recognizable phases: (1) episodic intoxication, or “euphoria,” (2) pharmacogenic dependence or drug-seeking behavior (addiction), and (3) the propensity to relapse after a period of abstinence.

Some of the symptoms of opioid intoxication have already been considered. In patients with severe pain or pain-anticipatory anxiety, the administration of opioids produces a sense of unusual well-being, a state that has traditionally been referred to as morphine euphoria. It should be emphasized that only a negligible proportion of such persons continue to use opioids habitually after their pain has subsided. The vast majority of potential addicts are not suffering from painful illnesses at the time they initiate opioid use, and the term euphoria is probably not an apt description of
The initial effects. These persons, after several repetitions, recognize a “high,” despite the subsequent recurrence of unpleasant, or dysphoric, symptoms (nausea, vomiting, and faintness as the drug effect wanes). One of our patients described the initial effect as “dying and going to heaven.” The repeated self-administration of the drug is the most important factor in the genesis of addiction. Regardless of how one characterizes the state of mind that is produced by episodic injection of the drug, the individual quickly discovers the need to increase the dose in order to obtain the original effects (tolerance). Although the initial effects may not be fully recaptured, the progressively increasing dose of the drug does relieve the discomfort that arises as the effects of each injection wear off. In this way a new pharmacogenically induced need is developed, and the use of opioids becomes self-perpetuating. At the same time a marked degree of tolerance is produced, so that enormous amounts of drugs, e.g., 5000 mg of morphine daily, can eventually be administered without the development of toxic symptoms.

The pharmacologic criteria of addiction, as indicated in the chapter on alcoholism, are tolerance and physical dependence. The latter refers to the symptoms and signs that become manifest when the drug is withdrawn following a period of continued use. These symptoms and signs constitute a specific clinical state, termed the abstinence or withdrawal syndrome (see later). The mechanisms that underlie the development of tolerance and physical dependence are not fully understood. However, it is known that opioids activate an opioid antinociceptive system (enkephalins, dynorphins, endorphins), which are opioid receptors and are located at many different levels of the nervous system (these are described in Chap. 8, on pain; see also the review of Fields).

The Opioid Abstinence Syndrome The intensity of the abstinence or withdrawal syndrome depends on the dose of the drug and the duration of addiction. The onset of abstinence symptoms in relation to the last exposure to the drug, however, is related to the pharmacologic half-life of the agent. With morphine, the majority of individuals receiving 240 mg daily for 30 days or more will show moderately severe abstinence symptoms following withdrawal. Mild signs of opiate abstinence can be precipitated by narcotic antagonists in persons who have taken as little as 15 mg of morphine or an equivalent dose of methadone or heroin three times daily for 3 days.

The abstinence syndrome that occurs in the morphine addict may be taken as the prototype. The first 8 to 16 h of abstinence usually pass asymptptomatically. At the end of this period, yawning, rhinorrhea, sweating, piloerection, and lacrimation become manifest. Mild at first, these symptoms increase in severity over a period of several hours and then remain constant for several days. The patient may be able to sleep during the early abstinence period but is restless, and thereafter insomnia remains a prominent feature. Dilatation of the pupils, recurring waves of “gooseflesh,” and twitchings of the muscles appear. The patient complains of aching in the back, abdomen, and legs and of “hot and cold flashes”; he frequently asks for blankets. At about 36 h the restlessness becomes more severe, and nausea, vomiting, and diarrhea usually develop. Temperature, respiratory rate, and blood pressure are slightly elevated. All these symptoms reach their peak intensity 48 to 72 h after withdrawal and then gradually subside. The opioid abstinence syndrome is rarely fatal (it is life-threatening only in infants). After 7 to 10 days, the clinical signs of abstinence are no longer evident, although the patient may complain of insomnia, nervousness, weakness, and muscle aches for several more weeks, and small deviations of a number of physiologic variables can be detected with refined techniques for up to 10 months (protracted abstinence).

Habitation, the equivalent of emotional or psychologic dependence, refers to the substitution of drug-seeking activities for all other aims and objectives in life. It is this feature that fosters relapse to the use of the drug long after the physiologic (“nonpurposive”) abstinence changes seem to have disappeared. The cause for relapse is not fully understood. Theoretically, fragments of the abstinence syndrome may remain as a conditioned response, and these abstinence signs may be evoked by the appropriate environmental stimuli. Thus, when a “cured” addict returns to a situation where narcotic drugs are readily available or in a setting that was associated with the initial use of drugs, the incompletely extinguished drug-seeking behavior may reassert itself.

The characteristics of addiction and of abstinence are qualitatively similar with all drugs of the opiate group as well as the related synthetic analgesics. The differences are quantitative and are related to the differences in dosage, potency, and length of action. Heroin is two to three times more potent than morphine, but the heroin withdrawal syndrome encountered in hospital practice is usually mild in degree because of the low dosage of the drug in the street product. Dilaudid (hydromorphone) is more potent than morphine and has a shorter duration of action; hence the addict requires more doses per day, and the abstinence syndrome comes on and subsides more rapidly. Abstinence symptoms from codeine, while definite, are less severe than those from morphine. The addiction liabilities of propoxyphene are negligible. Abstinence symptoms from methadone are less intense than those from morphine and do not become evident until 3 or 4 days after withdrawal; for these reasons methadone can be used in the treatment of morphine and heroin dependency (see further on). Meperidine addiction is of particular importance because of its high incidence among physicians and nurses. Tolerance to the drug’s toxic effects is not complete, so that the addict may show tremors, twitching of muscles, confusion, hallucinations, and sometimes convulsions. Signs of abstinence appear 3 to 4 h after the last dose and reach their maximum intensity in 8 to 12 h, at which time they may be worse than those of morphine abstinence.

As to the biologic basis of addiction, tolerance, and physical dependence, our understanding is still very limited. Experiments in animals have provided the first insights into the neurotransmitter and neuronal systems involved. As a result of microdialyzing opiates and their antagonists into the central brain structures of animals, it has been tentatively concluded that mesolimbic structures, particularly the nucleus accumbens, ventral tegmentum of the midbrain, and locus ceruleus are activated or depressed under conditions of repeated opiate exposure. Thus, chronic opiate usage increases the levels of certain intracellular messengers (possibly G proteins) that drive cyclic-AMP activity in the locus ceruleus and in the nucleus accumbens; blocking the expression of these proteins markedly increases the self-administration of opiates by addicted rats. As in alcoholism, certain subtypes of the serotonin and dopamine receptors in limbic structures have been implicated in the psychic aspects of addiction and habituation. These same structures are conceived as a common pathway for the impulse to human drives such as sex, hunger, and psychic fulfillment. The neurochemical mechanism of addiction has been reviewed by Cami and Farré.

The diagnosis of addiction is usually made when the patient admits to using and needing drugs. Should the patient conceal this fact, one relies on collateral evidence such as miosis, needle marks, emaciation, abscess scars, or chemical analyses. Meperidine ad-
dents are likely to have dilated pupils and twitching of muscles. The finding of morphine or opiate derivatives (heroin is excreted as morphine) in the urine is confirmatory evidence that the patient has taken or has been given a dose of such drugs within 24 h of the test. The diagnosis of opiate addiction is also at once apparent when the treatment of acute opiate intoxication precipitates a characteristic abstinence syndrome.

Treatment of the Opioid Abstinence Syndrome (Physical Dependence) One approach that has achieved some degree of success over the past 30 years has been the substitution of methadone for opioid, in the ratio of 1 mg methadone for 3 mg morphine, 1 mg heroin, or 20 mg meperidine. Since methadone is long-acting and effective orally, it need be given only twice daily by mouth—10 to 20 mg per dose being sufficient to suppress abstinence symptoms. After a stabilization period of 3 to 5 days, this dosage of methadone is reduced and the drug is withdrawn over a similar period. An alternative but probably less effective method has been the use of clonidine (0.2 to 0.6 mg twice a day for a week), a drug that counteracts most of the noradrenergic withdrawal symptoms; however, the hypotension that is induced by this drug may be a problem (Jasinski et al).

Recently, a rapid detoxification regimen that is conducted under general anesthesia has become popular in a number of centers as a means of treating opiate addiction. The technique consists of administering increasing doses of opioid receptor antagonists (naloxone or naltrexone) over several hours while the anesthetic and other features of the withdrawal syndrome are suppressed by the infusion of propofol or a similar anesthetic, supplemented by intravenous fluids. Medications such as clonidine and sedatives are also given in the immediate postanesthetic period. The addict is instructed to continue taking naltrexone for several days or weeks, a practice adopted by one of the outpatient treatment centers for addiction described later. There are substantial risks involved in this procedure, and several deaths have occurred for which reason it has been all but abandoned in our hospitals. Furthermore, a number of patients continue to manifest signs of withdrawal after the procedure and require continued hospitalization. These are as yet few careful studies of the efficacy and overall safety of this procedure.

Treatment of Opiate Habituation (Psychologic Dependence) This is in some ways far more demanding than the treatment of opioid withdrawal and can be best accomplished in special facilities and programs that are devoted wholly to the problem. These are available in most communities. The most effective ones have been the ambulatory methadone maintenance clinics, where more than 100,000 former heroin addicts are participating in rehabilitation programs approved by the Food and Drug Administration. Methadone, in a dosage of 60 to 100 mg daily (sufficient to suppress the craving for heroin), is given under supervision day by day (less often with long-acting methadone) for months or years. Various forms of psychotherapy and social service counseling often administered by former heroin addicts are integral parts of the program.

The results of methadone treatment are difficult to assess and vary considerably from one program to another. Even the most successful programs suffer an attrition rate of about 25 percent when they are evaluated after several years. Of the patients who remain, the majority achieve a high degree of social rehabilitation, i.e., they are gainfully employed and no longer engage in criminal behavior or prostitution.

The usual practice of methadone programs is to accept only addicts over the age of 16 years with a history of heroin addiction for at least 1 year. This leaves many adolescent addicts untreated. The number of addicts who can fully withdraw from methadone and maintain a drug-free existence is very small. This means that the large majority of addicts now enrolled in methadone programs are committed to an indefinite period of methadone maintenance, and the effects of such a regimen are uncertain.

An alternative method of ambulatory treatment of the opiate addict involves the use of narcotic antagonists, of which naloxone and naltrexone are the best known. The physical effects of abusing narcotics are thereby partially blocked, and there may be some degree of aversive conditioning if withdrawal symptoms are produced. Naltrexone is favored because it has a longer effect than naloxone, is almost free of agonist effects, and can be administered orally. Similar results have also been achieved with cyclazocine in a small number of highly motivated patients; this drug is administered orally in increasing amounts until a dosage of 2 mg/70 kg body weight is attained. The drug is taken twice daily (for 2 to 6 weeks) and is then withdrawn slowly.

More recently, interest has centered on the use of buprenorphine for the treatment of heroin (and cocaine) abuse. Buprenorphine is unique in that it has both opioid agonist and antagonist properties; it therefore mutes the effect of withdrawal and serves also as an aversive agent, like naltrexone. In addition, there is evidence, based on animal experiments and experience with small numbers of addicts, that it may be useful for the treatment of dual dependence on cocaine and opiates (see Mello and Mendelson). Buprenorphine has the additional advantage of being administered as a sublingual tablet. The FDA has recently approved its use.

Medical and Neurologic Complications of Opioid Use In addition to the toxic effects of the opioid itself, the addict may suffer a variety of neurologic and infectious complications resulting from the injection of contaminated adulterants (quinine, t alc, lactose, powdered milk, and fruit sugars) and of various infectious agents (injections administered by unsterile methods). The most important of these is HIV infection, but septicemia and endocarditis and viral hepatitis may also occur. Particulate matter that is injected with heroin or a vasculitis that is induced by chronic heroin abuse may cause stroke by an incompletely understood occlusion of cerebral arteries, with hemiplegia or other focal cerebral signs. Amblyopia, due probably to the toxic effects of quinine in the heroin mixtures, has been reported, as well as transverse myelopathy and several types of peripheral neuropathy. The spinal cord disorder expresses itself clinically by the abrupt onset of paraplegia with a level on the trunk below which motor function and sensation are lost or impaired and by urinary retention. Pathologically, there is an acute necrotizing lesion involving both gray and white matter over a considerable vertical extent of the thoracic and occasionally the cervical cord. In some cases a myelopathy has followed the first intravenous injection of heroin after a prolonged period of abstinence. We have also seen two cases of cervical myelopathy from heroin-induced stupor and a prolonged period of immobility with the neck hyperextended over the back of a chair or sofa.

In addition, we have observed several instances of a subacute progressive cerebral leukoencephalopathy after heroin use, similar to ones that occurred in Amsterdam in the 1980s, the result of inhalation of heroin pyrolysate or an adulterant (Wolters et al and Tan et al). In our cases the white matter changes were concentrated in the posterior regions of the hemispheres and in the internal capsules and, in one striking case, in the cerebellar white matter.
A similar leukoencephalopathy has also been reported in cocaine users, although a hypertensive encephalopathy or an adrenergic-induced vasculopathy may have played a role in these cases.

Damage to single peripheral nerves at the site of injection of heroin and from compression is a relatively common occurrence. However, bilateral compression of the sciatic nerves, the result of sitting or lying for a prolonged period in a stuporous state or in the lotus position while “stoned,” has occurred in several of our patients. In sciatic compression of this type, the peroneal branch has been more affected than the tibial, causing foot drop with less weakness of plantar flexion. More difficult to understand in heroin abusers is the involvement of other individual nerves, particularly the radial nerve, and painful affection of the brachial plexus, apparently unrelated to compression and remote from the sites of injection. Possibly in some instances there was a vasculitis affecting peripheral nerves.

An acute generalized myonecrosis with myoglobinuria and renal failure has been ascribed to the intravenous injection of adulterated heroin. Brawny edema and fibrosing myopathy (Volkman contracture) are the sequelae of venous thrombosis resulting from the administration of heroin and its adulterants by the intramuscular and subcutaneous routes. Occasionally there may be massive swelling of an extremity into which heroin had been injected subcutaneously or intramuscularly; infection and venous thrombosis appear to be involved in its causation.

The diagnosis of drug addiction or the suspicion of this diagnosis should always raise the possibility of an assortment of infectious complications: AIDS, syphilis, abscesses and cellulitis at injection sites, septic thrombophlebitis, hepatitis, and periarteritis. Tetanus, endocarditis (due mainly to *Staphylococcus aureus*), spinal epidural abscess, meningitis, brain abscess, and tuberculosis have occurred less frequently.

**SEDATIVE-HYPNOTIC DRUGS**

This class of drugs, also referred to as depressants, consists of two main groups. The first includes the barbiturates, meprobamate, and chloral hydrate. These drugs are now little used, having been largely replaced by a second group, the benzodiazepines, the most important of which are chlordiazepoxide (Librium), lorazepam (Ativan), alprazolam (Xanax), clonazepam (Klonipin), and diazepam (Valium). Closely related are the nonbenzodiazepine hypnotics, typified by zolpidem (Ambien). The advantages of the benzodiazepine drugs are their relatively low toxicity and addictive potential and their minimal interactions with other drugs.

**Barbiturates**

Despite the marked reduction in the medical use of barbiturates during the past three decades, the improper use of these drugs—particularly their nonmedical and illicit use—is still responsible for a sizeable number of suicides, accidental deaths, and addiction. In the past, about 50 barbiturates were marketed for clinical use, but only a few are now encountered with any regularity: pentobarbital (Nembutal), secobarbital (Seconal), amobarbital (Amytal), thiopental (Pentothal), and phenobarbital (Luminal). The first three are the ones most commonly abused. Barbiturates are also a component of combination preparations for the treatment of migraine (e.g., butalbital in Fiorinal).

**Mechanism of Action** All the common barbiturates are derived from barbituric acid; the differences between them depend on variations in the side chains of the parent molecule. The potency of each drug is a function of the ionization constant and lipid solubility. The higher its lipid solubility, the greater the drug’s potency and the quicker and briefer its action. The lowering of plasma pH increases the rate of entry of the ionized form into the brain. The action of barbiturates is to suppress neuronal transmission, presumably by enhancing GABA inhibition at pre- and postsynaptic receptor sites, and to reduce excitatory postsynaptic potentials. The major points of action in the CNS are similar to those of alcohol and other coma-producing drugs; impaired consciousness or coma relates to inactivation of neurons in the reticular formation of the upper brainstem. The liver is the main locus of drug metabolism, and the kidney is the method of elimination of the metabolites. All the barbiturates are similar pharmacologically and differ only in the speed of onset and duration of their action. The clinical problems posed by the barbiturates are different, however, depending on whether the intoxication is acute or chronic.

**Acute Barbiturate Intoxication** This results from the ingestion of large amounts of the drug, either accidentally or with suicidal intent. The latter is most frequently the act of a depressed person. The hysteric or sociopath may take an overdose as a suicidal gesture and become seriously intoxicated because of miscalculation or ignorance of the toxic dosage. Often the drug is taken while the individual is inebriated—a dangerous situation, since alcohol and barbiturate have an additive effect.

The symptoms and signs vary with the type and amount of drug as well as with the length of time that has elapsed since it was ingested. Pentobarbital and secobarbital produce their effects quickly, and recovery is relatively rapid. Phenobarbital induces coma more slowly, and its effects tend to be prolonged. In the case of long-acting barbiturates, such as phenobarbital and barbital, the hypnotic-sedative effect lasts 6 h or more after an average oral dose; with the intermediate-acting drugs such as amobarbital, 3 to 6 h; and with the short-acting drugs, secobarbital and pentobarbital, less than 3 h. Most fatalities follow the ingestion of secobarbital, amobarbital, or pentobarbital. The ingestion by adults of more than 3.0 g of these drugs at one time will prove fatal unless intensive treatment is applied promptly. The potentially fatal dose of pheno- barbital is 6 to 10 g. The lowest plasma concentration associated with lethal overdosage of phenobarbital or barbital has been approximately 60 mg/mL and that of amobarbital and pentobarbital, 10 mg/mL.

In regard to prognosis and treatment, it is useful to recognize three grades of severity of acute barbiturate intoxication. *Mild intoxication* follows the ingestion of approximately 0.3 g pentobarbital (the hypnotic dose in an unhabituated patient is 100 mg) or its equivalent. The patient is drowsy or asleep, although readily roused if called or shaken. The symptoms resemble those of alcohol intoxication. The patient thinks slowly, and there may be mild disorientation, lability of mood, impairment of judgment, slurred speech, drunken gait, and nystagmus. *Moderate intoxication* follows the ingestion of 5 to 10 times the oral hypnotic dose. The patient is stuporous, tendon reflexes are usually depressed or absent, and respirations are slow but not3

---

*Measurements and units may not be consistent across the document.*
Severe intoxication occurs with the ingestion of 10 to 20 times the oral hypnotic dose. The patient cannot be roused by any means, i.e., is comatose. Respiration is slow and shallow or irregular, and pulmonary edema and cyanosis may be present. The tendon reflexes are usually but not invariably absent. Most patients show no response to plantar stimulation, but in those who do, the responses are extensor. With deep coma, the corneal and gag reflexes may also be abolished. Ordinarily the pupillary light reflex is retained in severe intoxication and is lost only if the patient is asphyxiated; but in advanced cases, the pupils become miotic and poorly reactive, simulating opiate intoxication. At this point respiration is greatly depressed and oculocephalic and oculovestibular reflex responses are usually abolished. In the early hours of coma, there may be a phase of flexor or extensor posturing or rigidity of the limbs, hyperactive reflexes, ankle clonus, and extensor plantar signs; persistence of these signs indicates that anoxic damage has been added. The temperature may be subnormal, the pulse is thready and rapid, and the blood pressure is at shock levels. Failure of respiration to quicken on painful stimulation is an ominous sign.

There are few conditions other than barbiturate intoxication that cause a flaccid coma with small reactive pupils, hypothermia, and hypotension. A pontine hemorrhage may do so, but a hysterical trance or catatonic stupor do not present a problem in differential diagnosis. The use of gas and high-pressure liquid chromatography provides a reliable means of identifying the type and amount of barbiturate in the blood. A patient who has also ingested alcohol may be comatose with relatively low blood barbiturate concentrations. Contrariwise, the barbiturate addict may show only mild signs of intoxication with very high blood barbiturate concentrations.

In mild intoxication, the normal electroencephalogram (EEG) activity is replaced by fast (beta) activity, in the range of 20 to 30 cycles per second, and is most prominent in the frontal regions. In more severe intoxication, the fast waves become less regular and interspersed with 3- to 4-per-second slow activity; in still more advanced cases, there are short periods of suppression of all activity, separated by bursts of slow (delta) waves of variable frequency. In extreme overdosage, all electrical activity ceases. This is one instance in which a “flat” (isoelectric) EEG cannot be equated with brain death, and the effects are fully reversible unless anoxic damage has supervened.

**Management**

In mild or moderate intoxication, recovery is the rule and special treatment is not required except to prevent aspiration. If the patient is unresponsive, special measures must be taken to maintain respiration and prevent infection. An endotracheal tube should be inserted, with suctioning as necessary. Any risk of respiratory depression or underventilation requires the use of a positive-pressure respirator.

Hemodialysis or hemofiltration with charcoal may be used in comatose patients who have ingested long-acting barbiturates and these treatments are particularly advisable if anuria or uremia has developed. Treatment with analeptic drugs (e.g., picrotoxin, pentylentetrazol), which enjoyed a brief period of popularity, has been generally abandoned, since these drugs do not affect the rate of metabolism or the excretion of barbiturates.

Occasionally, in the case of a barbiturate addict who has taken an overdose of the drug, recovery from coma is followed by the development of abstinence symptoms, as described later.

**Barbiturate Addiction (Chronic Barbiturate Intoxication)**

Chronic barbiturate intoxication, like other drug addictions, tends to develop on a background of some psychiatric disorder, most commonly a depressive illness with symptoms of anxiety and insomnia. Alcoholics find that barbiturates effectively relieve their nervousness and tremor. As with other drug addictions, the incidence of barbiturism is particularly high in individuals with ready access to drugs, such as physicians, pharmacists, and nurses. The easy availability through the Internet of medications that contain barbiturates may increase dependence on these drugs (Romero et al).

The manifestations of barbiturism are much the same as those of alcohol intoxication. The barbiturate addict thinks slowly, exhibits increased emotional lability, and becomes untidy in dress and personal habits. The neurologic signs include dysarthria, nystagmus, and cerebellar incoordination. If the dosage is elevated rapidly, the signs of moderate or severe intoxication, as described earlier, become manifest.

A characteristic feature of chronic barbiturate intoxication is the development of a striking degree of tolerance. The average addict ingests about 1.5 g of a potent barbiturate daily and does not manifest signs of severe intoxication unless this amount is exceeded. However, tolerance to barbiturates does not develop as rapidly as to opiates. Most persons can ingest up to 0.4 g daily for as long as 3 months and then cease taking the drug without developing major withdrawal signs (seizures or delirium). With a dosage of 0.8 g daily for a period of 2 weeks to 2 months, abrupt withdrawal will result in serious symptoms in the majority of patients (see later).

**Barbiturate Abstinence, or Withdrawal, Syndrome**

Immediately following withdrawal, the patient seemingly improves over a period of 8 to 12 h, as the symptoms of intoxication diminish. Then a new group of symptoms develops, consisting of nervousness, tremor, insomnia, postural hypotension, and weakness. With chronic phenobarbital or barbital intoxication, withdrawal symptoms may not become apparent until 48 to 72 h after the final dose. Generalized seizures with loss of consciousness may occur, usually between the second and fourth days of abstinence but occasionally as long as 6 or 7 days after withdrawal. There may be a single seizure, several seizures, or, rarely, status epilepticus. Characteristically, in the withdrawal period, there is a greatly heightened sensitivity to photic stimulation, to which the patient responds with myoclonus or a seizure accompanied by paroxysmal changes in the EEG. The convulsive phase may be followed directly by a delusional-hallucinatory state or, as occurred in one of our cases (Romero et al), a full-blown delirium indistinguishable from delirium tremens, or a varying degree of improvement may follow the seizures before the delirium becomes manifest. Death has been reported under these circumstances. The abstinence syndrome may occur in varying degrees of completeness; some patients have seizures and recover without developing delirium, and others have a delirium without preceding seizures.

**Treatment of Chronic Barbiturate Intoxication and Abstinence**

This should be carried out in the hospital. If the diagnosis of addiction is made before signs of abstinence have appeared, the “stabilization dosage” should first be determined. This is the amount of short-acting barbiturate required to produce mild symptoms of intoxication (nystagmus, slight ataxia, and dysarthria). Usually 0.2 g of pentobarbital given orally every 6 h is sufficient for this purpose. Then a gradual withdrawal of the drug is undertaken, 0.1 g daily, the reduction being stopped for several days if abstinence symptoms appear. In this way, a severely addicted person can be
withdrawn in 14 to 21 days. The patient who presents with severe withdrawal symptoms, such as seizures, is generally given 0.3 to 0.5 g of phenobarbital intramuscularly and then enough to maintain a state of mild intoxication. Most other anticonvulsant medicines are ineffective against barbiturate withdrawal convulsions, and diazepines are only partially effective in our experience. Withdrawal should then be carried out as indicated earlier. If the abstinence symptoms are not severe, it is not necessary to reintoxicate the patient, but treatment can proceed along the lines laid down for other forms of delirium and confusion. After recovery has taken place, whether from acute or chronic intoxication, the psychiatric problem requires evaluation and an appropriate plan of therapy.

### Chlortal Hydrate

This is the oldest and one of the safest, most effective, and most inexpensive of the sedative-hypnotic drugs. After oral administration, chlortal hydrate is reduced rapidly to trichloroethanol, which is responsible for the depressant effects on the CNS. A significant portion of the trichloroethanol is excreted in the urine as the glucuronide, which may give a false-positive test for glucose.

Tolerance and addiction to chlortal hydrate develop only rarely; for this reason it is an appropriate medication for the management of insomnia. Poisoning with chlortal hydrate is a rare occurrence and resembles acute barbiturate intoxication except for the finding of miosis, which is said to characterize the former. Treatment follows along the same lines as for barbiturate poisoning. Death from poisoning is due to respiratory depression and hypotension; patients who survive may show signs of liver and kidney disease.

Paraldehyde, another member of this group of sedative drugs, is no longer being manufactured in the United States, and chlortal hydrate is now available mainly as an elixir for pediatric use.

### Benzodiazepines

With the introduction of chlordiazepoxide in 1960 and the benzodiazepine drugs that followed (particularly diazepam), the older sedative drugs (barbiturates, paraldehyde, chlortal hydrate) have become virtually obsolete. Indeed, the benzodiazepines are among the most commonly prescribed drugs in the world today. According to Hollister, 15 percent of all adults in the United States use a benzodiazepine at least once yearly and about half this number use the drug for a month or longer. As mentioned earlier, these drugs, compared with the older sedatives, have relatively minor hypnotic effects and low abuse potential and are relatively safe when taken in overdose.

The benzodiazepines have been prescribed frequently for the treatment of anxiety and insomnia, and they are especially effective when the anxiety symptoms are severe. Also, they have been used to control overactivity and destructive behavior in children and the symptoms of alcohol withdrawal in adults. Diazepam is particularly useful in the treatment of delirious patients who require parenteral medication. The benzodiazepines possess anticonvulsant properties, and the intravenous use of diazepam, lorazepam, and midazolam is an effective means of controlling status epilepticus, as described on page 297. Diazepam in massive doses has been used with considerable success in the management of muscle spasm in tetanus and in the “stiff man” syndrome (page 1279). Diazepam has been far less successful in the treatment of extrapyramidal movement disorders and dystonic spasms. Alprazolam (Xanax) has a central place in the treatment of panic attacks and other anxiety states, as an adjunct in some depressive illnesses, and in behavioral disturbances in Alzheimer disease. It seems, however, to create more dependence than some of the others in its class.

Other important benzodiazepine drugs are flurazepam (Dalmane), triazolam (Halcion), chlorazepate (Tranxene), temazepam (Restoril), and other newer varieties, all widely used in the treatment of insomnia (page 340), and clonazepam (Klonopin), which is useful in the treatment of myoclonic seizures (page 274) and intention myoclonus (page 89). Midazolam (Versed), a short-acting parenteral agent, is given frequently to achieve the brief sedation required for procedures such as MRI or endoscopy and is useful in the treatment of status epilepticus, however, it is known to cause respiratory arrest on occasion. Lorazepam (Ativan) and oxazepam (Serax) are said to be preferable to other benzodiazepines in treating the elderly and those with impaired liver function. Many other benzodiazepine compounds have appeared in recent years, but a clear advantage over the original ones remains to be demonstrated (Hollister; Piirdsky and Cohn).

The popularly used sleeping medication, Zolpidem (Ambien) differs from the benzodiazepines structurally but is pharmacologically similar.

The benzodiazepine drugs, like barbiturates, have a depressant action on the CNS by binding to specific receptors on GABA inhibitory systems. The benzodiazepines act in concert with GABA to open chloride ion channels and hyperpolarize postsynaptic neurons and reduce their firing rate. The primary sites of their action are the cerebral cortex and limbic system, which accounts for their anticonvulsive and anxiolytic effects. While quite safe in the recommended dosages, they are far from ideal. They frequently cause unsteadiness of gait and drowsiness and at times syncpe, confusion, and impairment of memory, especially in the elderly. If taken in large doses, the benzodiazepines can depress the state of consciousness, resembling that of other sedative-hypnotic drugs but with less respiratory suppression and hypotension. Flumazenil, a specific pharmacologic antagonist of the CNS effects of benzodiazepines, rapidly but briefly reverses most of the symptoms and signs of benzodiazepine overdose. It acts by binding to CNS diazepine receptors and thereby blocking the activation of inhibitory GABA-ergic synapses. Flumazenil may also have diagnostic utility in cases of coma of unknown etiology and in hepatic encephalopathy (see page 968).

Signs of physical dependence and true addiction, though relatively rare, undoubtedly occur in chronic benzodiazepine users, even in those taking therapeutic doses. The withdrawal symptoms are much the same as those that follow the chronic use of other sedative drugs (anxiety, jitteriness, insomnia, seizures) but may not appear until the third day after the cessation of the drug and may not reach their peak of severity until the fifth day (Hollister). In chronic benzodiazepine users, the gradual tapering of dosage over a period of 1 to 2 weeks minimizes the withdrawal effects. However, we have observed numerous cases over the years in which the cessation of moderate doses of chronically used diazepines has resulted in one or more seizures. This is likely to happen when the patient is hospitalized for other reasons and the accustomed sleeping medication is omitted.

### Carbonic Acid Derivatives

These drugs are capable of modest depressant action and are effective in relieving mild degrees of nervousness, anxiety, and mus-
cle tension. Meprobamate (Equanil, Miltown) is the best-known member of this group. It was the first of the “new” (postbarbiturate) antianxiety drugs, a chemical variant of the weak and ineffective muscle relaxant mephenesin. With average doses (400 mg three or four times a day), the patient is able to function quite effectively; larger doses cause ataxia, drowsiness, stupor, coma, and vasomotor collapse.

Meprobamate has turned out to have the same disadvantages as the barbiturates, including death from overdosage. Addiction to meprobamate may occur, and if four or more times the daily recommended dose is taken over a period of weeks to months, withdrawal symptoms (including convulsions) may appear. Because of this tendency to produce physical dependence and other disadvantages (serious toxic reactions and a high degree of sedation), meprobamate and its congeners are now seldom used except illicitly.

**Buspirone** A new class of antianxiety agents, exemplified by the selective 5-HT2 serotoninergic agent buspirone (BuSpar), is chemically and pharmacologically different from the benzodiazepines, barbiturates, or other sedatives. Its distinctive nature is confirmed by the observation that it does not block the withdrawal syndrome of other sedative-hypnotic drugs. Because of its apparently reduced potential for abuse and tolerance, it is not included in the list of controlled pharmaceutical substances in the United States, but adverse interactions with MAO inhibitors are known. Its use with other psychotropic drugs is still under investigation.

**Antipsychosis Drugs**

In the mid-1950s, a large series of pharmacologic agents, originally referred to as tranquilizers (later, as psychotropic or neuroleptic drugs), came into prominent use—mainly for the control of schizophrenia, psychotic states associated with “organic brain syndromes,” and affective disorders (depression and manic-depressive disease). The mechanisms by which these drugs ameliorate disturbances of thought and affect in psychotic states are not fully understood, but presumably they act by blocking the postsynaptic mesolimbic dopamine receptors of which there are four subtypes, termed D1 through D4 on neuronal membranes (see Table 4-2 and discussion of dopamine receptor subtypes on page 60). The D2 receptors are located mainly in the frontal cortex, hippocampus, and limbic cortex, and the D1 receptors, in the striatum as discussed in Chap. 4. The blockade of dopamine receptors in the striatum is probably responsible for the parkinsonian side effects of this entire class of drugs, and the blockade of another dopaminergic (tuberoinfundibular) system, for the increased prolactin secretion by the pituitary. These drugs also produce some adrenergic blocking effect. The newer “atypical” antipsychotic drugs, typified by clozapine (Clozaril), apparently achieve the same degree of D2 and D1 blockade in the temporal and limbic lobes while exhibiting substantially less antagonistic activity in the striatum—accounting also for their lesser parkinsonian side effects. These drugs also block subsets of serotonin receptors.

Since the introduction in the 1950s of the phenothiazine chlorpromazine as an anesthetic agent and the serendipitous discovery of its antipsychotic effect on schizophrenia, a large number of antipsychotic drugs have been marketed for clinical use. No attempt is made here to describe or even list all of them. Some have had only an evanescent popularity, and others have yet to prove their value. Chemically, these compounds form a heterogeneous group. Eight classes of them are of particular clinical importance: (1) the phenothiazines; (2) the thioxanthenes; (3) the butyrophenones; (4) the rauwolfia alkaloids; (5) an indole derivative, loxapine (Lolitane), and a unique dihydroindalone, molindone (Moban); (6) a diphenylbutylpiperidine, pimozide (Orap); (7) dibenzodiazepines, typified by clozapine (Clozaril) and olanzapine (Zyprexa); and (8) a benzisoxazole derivative, risperidone (Risperdal). The last four of these drugs were introduced more recently than the others and hence have had a more limited trial. Molindone and loxapine are about as effective as the phenothiazines in the management of schizophrenia, and their side effects are similar although claims have been made that they are less likely to induce tardive dyskinesias and seizures. Their main use is in patients who are not responsive to the older drugs or who suffer intolerable side effects from them. The antipsychotic agents in the class of clozapine have attracted great interest, since—as already mentioned—they are associated with relatively fewer extrapyramidal side effects. For this reason, they are particularly favored in controlling the confusion and psychosis of parkinsonian patients. The other new class of drugs, of which risperidone is the main example, also has fewer extrapyramidal side effects than the phenothiazines and a more rapid onset of action than the traditional antipsychotic medications. Pimozide may be useful in the treatment of haloperidol-refractory cases of Gilles de la Tourette syndrome (page 95); its main danger is its tendency to produce cardiac arrhythmias.

**Phenothiazines**

This group comprises some of the most widely used tranquilizers, such as the phenothiazines chlorpromazine (Thorazine), promazine (Sparine), trifluromazine (Vesprin), prochlorperazine (Compazine), perphenazine (Trilafon), fluphenazine (Permitil, Prolixin), thioridazine (Mellaril), mesoridazine (Serentil), and trifluoperazine (Stelazine). In addition to their psychotherapeutic effects, these drugs have a number of other actions, so that certain members of this group are used as antiemetics (prochlorperazine) and antihistaminics (promethazine).

The phenothiazines have had their widest application in the treatment of the major psychoses, namely schizophrenia and, to a lesser extent, manic-depressive psychosis. Under the influence of these drugs, many patients who would otherwise be hospitalized are able to live at home and even work productively. In the hospital, the use of these drugs has greatly facilitated the care of hyperactive and combative patients (see Chaps. 57 and 58 for details of this clinical use).

Side effects of the phenothiazines are frequent and often serious. All of them may cause a cholestatic type of jaundice, agranulocytosis, convulsive seizures, orthostatic hypotension, skin sensitivity reactions, mental depression, and, most importantly, immediate or delayed extrapyramidal motor disorders. The neuroleptic malignant syndrome is the most extreme complication and is discussed separately further on. The following types of extrapyramidal symptoms, also discussed on page 94, have been noted in association with all of the phenothiazines as well as the butyrophenones and, to a lesser extent, metoclopramide (Reglan) and pimozide, which block dopaminergic receptors:

1. A parkinsonian syndrome is the most common complication—masked facies, slight symmetric tremor, reduced blinking, generalized rigidity, shuffling gait, and slowness of
movement. These symptoms may appear after several days of drug therapy but more often after several weeks. Suppression of dopamine in the striatum (similar to the effect of loss of dopaminergic nigral cells that project to the striatum) is presumably the basis of the parkinsonian signs.

2. **Acute dyskinetic and dystonic reactions**, taking the form of involuntary movements of lower facial muscles (mainly around the mouth) and protrusion of the tongue (buccolingual or oral-masticatory syndrome), dysphagia, torticollis and retrocollis, oculogyric crises, and tonic spasms of a limb. These complications usually occur early in the course of administration of the drug, sometimes after the initial dose, in which case they recede dramatically upon immediate discontinuation of the drug and the intravenous administration of diphenhydramine hydrochloride (Benadryl) or benztropine (Cogentin).

3. **Akathisia**—an inner restlessness reflected by a persistent shifting of the body and feet and an inability to sit still, such that the patient paces the floor or jiggles the legs constantly (see page 97). Of all the phenothiazines, molindone has a special tendency to cause akathisia. This disorder often responds to oral propranolol.

4. **Tardive dyskinesia**—a group of late and persistent complications of neuroleptic therapy, which may continue after removal of the offending drug, comprises lingual-facial-buccal-cervical dyskinesias, choreoathetotic and dystonic movements of the trunk and limbs, diffuse myoclonus (rare), perioral tremor (“rabbit” syndrome), and dysartria or anarthria. Snyder has postulated that the movements are due to hypersensitivity of dopamine receptors in the basal ganglia, secondary to prolonged blockade of the receptors by antipsychotic medication. Baldessarini estimates that as many as 40 percent of patients receiving long-term antipsychotic medication develop tardive dyskinesia of some degree. A pathology has never been ascertained and the effect is likely due to subcellular pathophysiologic alterations in the basal ganglia. Treatment is discussed later.

5. The neuroleptic malignant syndrome is discussed separately later because of its gravity and requirement for specific treatment.

**Butyrophenones**

Haloperidol (Haldol) is the only member of this group approved for use as an antipsychotic in the United States. It has much the same therapeutic effects as the phenothiazines in the management of acute psychoses and shares the same side effects as the phenothiazines, but exhibits little or no adrenergic blocking action. It is an effective substitute for the phenothiazines in patients who are intolerant of the latter drugs, particularly of their autonomic effects. It is also one of the main drugs for the treatment of Gilles de la Tourette syndrome (the other being pimozide; see page 95) and the movement disorder of Huntington chorea.

**Treatment of Neuroleptic Side Effects**

As indicated earlier, acute dystonic spasms usually respond to diphenhydramine (Benadryl). Administration of antiparkinsonian drugs of the anticholinergic type (trihexyphenidyl, procyclidine, and benztropine) may hasten recovery from some of the acute symptoms. The purely parkinsonian syndrome usually improves as well, but the tardive dyskinesias stand apart because they may persist for months or years and may be permanent.

Oral, lingual, and laryngeal dyskinesias of the tardive type are affected relatively little by any antiparkinsonian drugs. Amantadine (Symmetrel) in doses of 50 to 100 mg tid has been useful in a few of the cases of postphenothiazine dyskinesia. Other drugs such as benztprine have been tried in the treatment of regional and more generalized tardive dyskinesia, with uncertain results. Nevertheless, there is a tendency for most of the obstinate forms to subside slowly even after several years of unsuccessful therapy. Once a tardive syndrome has been identified, several authoritative clinicians recommend a gradual reduction in the dose of the antipsychosis medication to the minimum necessary for the control of psychotic symptoms. Some reports favor the substitution of one of the newer “atypical” antipsychotic medications but no systematic study of their effectiveness has been undertaken.

For severe and recalcitrant cases, particularly those involving axial dystonias and similar disabling features, Fahn recommends administration of the dopamine depleting drug tetrabenazine (similar but faster in action and less toxic than reserpine). This medication is given in doses of 75 to 300 mg per day. Jankovic and Beach report an 83 percent success rate using this approach for tardive dyskinesias. The medication is not easily available in the United States but can be obtained from Canada at this time. The use of low doses of antipsychotic drugs and frequent drug holidays, especially in the more susceptible older patients, may help to prevent the development of tardive dyskinesia.

**Neuroleptic Malignant Syndrome**

This is the most dreaded complication of phenothiazine and haloperidol use; rare instances have been reported after the institution or the withdrawal of L-dopa and similar dopaminergic agents. Its incidence has been calculated to be only 0.2 percent of all patients receiving neuroleptics (Caroff and Mann), but its seriousness is underscored by a mortality rate of 15 to 30 percent if not recognized and treated promptly. It may occur days, weeks, or months after neuroleptic treatment is begun. The syndrome consists of rigidity, stupor, unstable blood pressure, variable hyperthermia, diaphoresis and other signs of autonomic dysfunction, high serum creatine kinase (CK) values (up to 60,000 units), and, in some cases, renal failure due to myoglobinuria. The syndrome was first observed in patients treated with haloperidol, and since then other neuroleptic drugs have been incriminated, particularly the highly potent thioxanthine derivatives and the phenothiazines—chlorpromazine, fluphenazine, and thioridazine—but also, on rare occasions, the less potent drugs that are used to control nausea, such as promethazine. It has become evident that the newer antipsychotic drugs, and specifically olanzapine, are also capable of inducing the syndrome but the risk in comparison to the first generation of antipsychotic drugs has not been established.

If treatment of the neuroleptic malignant syndrome is started early, when consciousness is first altered and the temperature is rising, bromocriptine in oral doses of 5 mg tid (up to 20 mg tid) will terminate the condition in a few hours. If oral medication can no longer be taken because of the patient’s condition, dantrolene, 0.25 to 3.0 mg intravenously, may be lifesaving. Once coma has supervened, shock and anuria may prove fatal or leave the patient in a vegetative state. The rigors during high fever may cause muscle damage and myoglobinuria, and the circulatory collapse may lead to hypoxic-ischemic brain injury.
Meningitis, heat stroke, lithium intoxication, catatonia, and acute dystonic reactions figure in the differential diagnosis. Of course, neuroleptic medication must be discontinued as soon as any of the severe extrapyramidal reactions are recognized. It has been common practice to avoid future administration of the offending neuroleptic, but the risk of using another class of antipsychotic agents has not been fully addressed.

The neuroleptic malignant syndrome bears an uncertain relationship to malignant hyperthermia by way of its clinical aspects but also in its response to bromocriptine and dantrolene (see later). Malignant hyperthermia is an inherited disorder that, in susceptible individuals, is triggered by inhalation anesthetics and skeletal muscle relaxants (page 1272). This disorder was described before the introduction of neuroleptic drugs and in a small proportion of cases has been related to a mutation of the ryanodine receptor gene on chromosome 19q. A genetic factor is also suspected to underlie the neuroleptic malignant syndrome (a polymorphism in the D2 receptor gene; see Suzuki et al), possibly provoked by fatigue and dehydration. There is no evidence that the occurrence of one of these syndromes confers a susceptibility to the other.

It hardly needs to be pointed out that the antipsychotic drugs have been much overused. This would be suspected just from the frequency with which they are being prescribed. These medications have specific indications, noted earlier and in Chaps. 56, 57, and 58, and the physician should be certain of the diagnosis and the indication for their use. That the neuroleptic drugs can produce tardive dyskinesia in nonpsychotic patients is reason enough not to prescribe them for nervousness, apprehension, anxiety, mild depression, insomnia, and the many normal psychologic reactions to trying environmental circumstances. These drugs are not curative but only suppress or partially alleviate symptoms, and they should not serve as a substitute for, or divert the physician from, the use of other measures for the relief of abnormal mental states.

**ANTIDEPRESSION MEDICATIONS**

Four classes of drugs—the monoamine oxidase (MAO) inhibitors, the tricyclic compounds, the serotoninergic drugs, and lithium—are particularly useful in the treatment of depressive illnesses. The adjective antidepressant refers to their therapeutic effect and is employed here in deference to common clinical practice. Antidepressive or antidepressant drugs would be preferable, since the term depressant still has a pharmacologic connotation that does not necessarily equate with the therapeutic effect. For example, barbiturates and chloral hydrate are depressants in the pharmacologic sense and mood elevators or antidepressants in the clinical sense.

**Monoamine Oxidase Inhibitors**

The observation that iproniazid, an inhibitor of MAO, had a mood-elevating effect in tuberculous patients initiated a great deal of interest in compounds of this type and led quickly to their exploitation in the treatment of depression. Iproniazid proved exceedingly toxic to the liver and was soon taken off the market, as were several subsequently developed MAO inhibitors; but other drugs in this class, much better tolerated, are still available. These include isocarboxazid (Marplan), phenelzine (Nardil), and tranylcypromine (Parnate), the latter two being the more frequently used. Tranylcypromine, which bears a close chemical resemblance to dextroamphetamine, may produce unwanted stimulation, but the most common adverse effect of all the MAO inhibitors is postural hypotension. Also, interactions with a wide array of other drugs and ingested substances may induce severe hypertension.

Monoamine oxidase is located on the outer surface of the mitochondria in neurons and is utilized in the catabolism of catecholamines (Coyle). In the gut and liver, this enzyme normally serves to deaminate phenethylamine, tyramine, and tryptamine—the products of protein catabolism. Inhibition of MAO allows these dietary amines, which have an amphetamine-like action, to enter the systemic circulation in increased quantities, thus releasing noradrenaline from sympathetic nerve endings and increasing heart rate and blood pressure. Probably more relevant to their action as antidepressants, the MAO inhibitors also have in common the ability to block the intraneuronal oxidative deamination of naturally occurring amines (norepinephrine, epinephrine, and serotonin), and it has been suggested that the accumulation of these substances is responsible for the antidepressant effect. However, many enzymes other than monoamine oxidase are inhibited by MAO inhibitors, and the latter drugs have numerous actions unrelated to enzyme inhibition. Furthermore, many agents with antidepressant effects like those of the MAO inhibitors do not inhibit MAO. Therefore, one cannot assume that the therapeutic effect of these drugs has a direct relation to MAO inhibition in the brain.

The MAO inhibitors must be dispensed with great caution and constant awareness of their potentially serious side effects. They may at times cause excitement, restlessness, agitation, insomnia, and anxiety, occasionally with the usual dose but more often with an overdose. Mania and convulsions may occur (especially in epileptic patients). Other side effects are muscle twitching and involuntary movements, urinary retention, retching, tachycardia, jaundice, visual impairment, enhancement of glaucoma, impotence, sweating, muscle spasms, paresthesias, and a serious degree of orthostatic hypotension.

*Patients taking MAO inhibitors must be warned against the use of phenothiazines, CNS stimulants, tricyclic and serotoninergic antidepressants (see later), and also sympathomimetic amines and tyramine.* The combination of an MAO inhibitor and any of these drugs or amines may induce severe hypertension, atrial and ventricular arrhythmia, pulmonary edema, stroke, and even death. Symptomimetic amines are contained in some commonly used cold remedies, nasal sprays, nose drops, and certain foods—aged cheese, beer, red wine, pickled herring, sardines, sausages, and preserved meat or fish. Exaggerated responses to the usual dose of meperidine (Demerol) and other narcotic drugs have also been observed sporadically; in these cases, respiratory function may be depressed to a serious degree, and hyperpyrexia, agitation, and pronounced hypotension may occur as well, sometimes with fatal issue. Unpredictable side effects may also accompany the simultaneous administration of barbiturates and MAO inhibitors. The abrupt occurrence of severe occipital headache, nausea, vomiting, pupillary dilation, or visual blurring should suggest a hypertensive crisis. Treatment is with intravenous phentolamine 5 mg, nitroprusside, labetalol, or a calcium channel blocker administered slowly to prevent hypotension. Overdosage may lead to coma, for which there is no treatment other than supportive care.

The therapeutic use of MAO inhibitors is discussed in Chaps. 56 and 57.

**Tricyclic Antidepressants**

Soon after the first successes with MAO inhibitors, a new class of tricyclic compounds appeared. The first was imipramine (Tofranil),...
soon followed by amitriptyline (Elavil) and then by desipramine (Norpramin) and nortriptyline (Pamelor). Another important dibenzoazepine derivative is carbamazepine (Tegretol), which is widely used in the control of seizures but has also found a place in the treatment of lancinating neuropathic and myelopathic pain and possibly of depression and mood instability. Subsequently, a number of additional antidepressant drugs were introduced. Included here are variants of the conventional tricyclic drugs (amoxapine, protriptyline, trimipramine, doxepin), tetracyclics (maprotiline), bicyclics (zimeldine), and others (trazodone, bupropion). A full account of these drugs, which will not be attempted here, can be found in the monographs of Hollister and of Piroldsky and Cohn.

The mode of action of these agents is not fully understood, but there is evidence that they block the reuptake of amine neurotransmitters, both norepinephrine and serotonin. Blocking this amine pump mechanism (called the presynaptic plasma transporter), which ordinarily terminates synaptic transmission, permits the persistence of neurotransmitter substances in the synaptic cleft and does no more than support the hypothesis that endogenous depression is associated with a deficiency of noradrenergic or serotonergic transmission.

The tricyclic antidepressants and the serotoninergic drugs discussed in the next section, are presently the most effective drugs for the treatment of patients with depressive illnesses, the former being particularly useful for those with anergic depressions associated with hyposomnia, early morning awakening, and decreased appetite and libido. The side effects of the tricyclic drugs are less frequent and far less serious than those of the MAO inhibitors.

The tricyclic (dibenzoazepine) compounds are potent anticholinergic agents, which account for their most prominent and serious side effects—orthostatic hypotension and urinary bladder weakness. They may also occasionally produce CNS excitation—leading to insomnia, agitation, and restlessness—but usually these effects are readily controlled by small doses of benzodiazepines given concurrently or in the evenings. Rarely, they may cause ataxia and blood dyscrasias. As indicated earlier, the tricyclic drugs should not be given with an MAO inhibitor; serious reactions have occurred when small doses of imipramine were given to patients who had discontinued the MAO in the previous days or week. It must be repeated that both the MAO inhibitors and the tricyclic antidepressants are dangerous drugs when taken in excess.

Tricyclic compounds are a frequent cause of accidental poisoning and a favored suicidal instrument of depressed patients. It is common for the intoxicated patient to have taken several drugs, in which case chemical analyses of the blood and urine are particularly helpful in determining the drugs involved and in sorting out therapeutic and toxic concentrations. Mortality from overdose is mostly due to cardiac disturbances, particularly tachyarrhythmias and impaired conduction (atrioventricular block). Treatment consists of gastric aspiration and instillation of activated charcoal and the addition of physostigmine to reverse serious arrhythmias; the persistence of neurotransmitter substances in the synaptic cleft and the short duration of action of physostigmine require that frequent doses be given. Dialysis is of no value because of the low plasma concentrations of the drug.

Serotonin Reuptake Inhibitors and Related Drugs

The selective serotonin reuptake inhibitors (SSRIs) constitute a newer class of antidepressants; paroxetine (Paxil), fluoxetine (Prozac), and sertraline (Zoloft) are the ones most often used, but others are being developed at a rapid pace. They act presumably by inhibiting the reuptake of serotonin and to a lesser extent of norepinephrine, somewhat like the effect of a tricyclic antidepressant. This results in a potentiation of the actions of these neurotransmitters. Because they do not bind as avidly as tricyclic drugs to the muscarinic and adrenergic receptors in the brain, they produce fewer side effects, but some patients complain of anxiety or insomnia when they are first introduced. As with the tricyclic agents, the concomitant administration of MAO inhibitors is hazardous. There should be a period of at least 1 week between the administration of these two classes of drugs to allow for the washout of the last agent used. Of the several related drugs such as venlafaxine (Effexor), nefazodone (Serzone), citalopram (Celexa), and bupropion (Wellbutrin), each has a novel structure that is not analogous to that of the other categories of antidepressants. They are believed to act similarly to the SSRI class by inhibiting the reuptake of serotonin and norepinephrine. These newer drugs share most of the side effects of the SSRI drugs, including the danger of concomitant MAO inhibitor administration.

The symptoms of a “serotonin syndrome” that results from excessive intake or from the concurrent use of MAO inhibitors include confusion, restlessness, myoclonus, shivering, and diaphoresis, as summarized by Sternbach.

The risk of seizures related to the taking of certain of these medications has been much discussed. For the most part, the risk is quite small but there is little information to guide their use in known epileptics. Several studies suggest that the frequency of convulsions may increase in such patients. Bupropion has been particularly associated with seizures in about 0.5 percent of patients treated at higher dose levels (over 400 mg per day) and this drug should not be used in individuals with a history of seizures.

The SSRI drugs are well tolerated, may be effective in a shorter time than the tricyclic agents, and are very popular at the moment, but their long-term therapeutic usefulness in comparison with their predecessors remains to be determined (see review of Richelson). Fluoxetine has also been used with benefit in a group of autistic children (page 890). Constipation, dry mouth, and reduced sexual potency are to be expected to some, but varying degrees. Hyponatremia is a rare complication.

Lithium

The discovery of the therapeutic effects of lithium salts in mania has led to its widespread use in the treatment of manic-depressive disease (bipolar disorder). The drug has proved relatively safe, and blood levels are easily monitored. Its value is much more certain in treatment of the manic phase of bipolar disorder and prevention of recurrences of cyclic mood shifts than it is in treatment of anxiety and depression. Guidelines for the clinical use of lithium are given in Chap. 57. Its mechanism of action is unclear, but there is experimental evidence that lithium blocks the stimulus-induced release of norepinephrine and enhances the reuptake of this amine—the opposite, in a sense, of what occurs with the other classes of antidepressants.

With blood levels of lithium in the upper therapeutic range, it is not uncommon to observe a fast-frequency action tremor or asterixis, together with nausea, loose stools, fatigue, polydipsia, and polyuria. These symptoms usually subside with time. Above a level of 1.5 to 2 meq/L, particularly in patients with impaired renal function or in those taking a thiazide diuretic, serious intoxication becomes manifest—clouding of consciousness, confusion, delirium,
dizziness, nystagmus, ataxia, stammering, diffuse myoclonic twitching, and nephrogenic diabetes insipidus. Vertical (down-beating) nystagmus and opsonoclasts may also be prominent. This clinical state, particularly confusion and myoclonus associated with sharp waves in the EEG, may mimic Creutzfeldt-Jakob disease (page 653), but there should be no problem in diagnosis if the setting of the illness and the administration of lithium are known. At a blood lithium concentration of 3.5 meq/L, these symptoms are replaced by stupor and coma, sometimes with convulsions, and may prove fatal.

Discontinuing lithium in the intoxicated patient, which is the initial step in therapy, does not result in immediate disappearance of toxic symptoms. This may be delayed by a week or two, and the diabetes insipidus may persist even longer. Fluids, sodium chloride, aminophylline, and acetazolamide promote the excretion of lithium. Lithium coma may require hemodialysis, which has proved to be the most rapid means of reducing the blood lithium concentration.

**STIMULANTS**

Drugs that act primarily as CNS stimulants have a relatively limited therapeutic use but assume clinical importance for other reasons. Some members of this group, e.g., the amphetamines, are much abused, and others are not infrequent causes of poisoning.

**Amphetamines (Benzedrine, Adderall)** These drugs and dextroamphetamine, its D-isomer, are powerful analeptics (CNS stimulants) and in addition have significant hypertensive, respiratory-stimulant, and appetite-depressant effects. They are effective in the management of narcolepsy but have been much more widely and sometimes indiscriminately used for the control of obesity, the abolition of fatigue, and the treatment of hyperactivity in children. Undoubtedly, they are able to reverse fatigue, postpone the need for sleep, and elevate mood, but these effects are not entirely predictable, and the user must pay for the period of wakefulness with even greater fatigue and often with depression that may follow. The intravenous use of a high dose of amphetamine produces an immediate feeling of ecstasy, the “flash.”

Because of the popularity of the amphetamines and the ease with which they can be procured, instances of acute and chronic intoxication are observed frequently. The toxic signs are essentially an exaggeration of the analeptic effects—restlessness, excessive speech and motor activity, tremor, and insomnia. Severe intoxication may give rise to hallucinations, delusions, and changes in affect and thought processes—a state that may be indistinguishable from paranoid schizophrenia. An amphetamine associated vasculitis and intracerebral and subarachnoid hemorrhage are well-recognized but rare complications of chronic intoxication (Harrington et al), and they may occur after acute use as well. Similar cerebrovascular complications may appear with sympathomimetic agents contained in over-the-counter cold medications and in diet aids. Phenylpropanolamine has been implicated most often, but ephedrine and similar agents rarely have the same effects and induce a vasculopathy. The pathogenesis of the vascular lesion is unknown (both vasospasm and arteritis have been reported), and the same state occurs with cocaine, as described below.

Chronic use of amphetamines can lead to a high degree of tolerance and psychologic dependence. Withdrawal of the drug after sustained oral or intravenous use is regularly followed by a period of prolonged sleep (a disproportionate amount of which is REM sleep), from which the patient awakens with a ravenous appetite, muscle pains, and feelings of profound fatigue and depression. Treatment consists of discontinuing the use of amphetamine and administering antipsychotic drugs. Nitrites may be useful if the blood pressure is markedly elevated.

**Methylphenidate (Ritalin)** This drug has much the same type of action as dextroamphetamine and is effective in the treatment of narcolepsy. Paradoxically, like amphetamine, it is useful in the management of attention-deficit hyperactivity disorder in children, and its chronic usage in moderate doses results in no deleterious effects (see page 511).

**HALLUCINOGENS**

Included in this category is a heterogeneous group of drugs, the primary effect of which is to alter perception, mood, and thinking out of proportion to other aspects of cognitive function and consciousness. This group of drugs comprises cocaine, lysergic acid derivatives [e.g., lysergic acid diethylamide (LSD)], phenylethylamine derivatives (mescaline or peyote), psilocybin, certain indolic derivatives, cannabis (marijuana), phencyclidine (PCP), and a number of less important compounds. They are also referred to as psychoactive or psychotomimetic drugs or as hallucinogens and psychedelics—but none of these names is entirely suitable. The problems raised by the nontherapeutic use of these drugs, which has declined somewhat but is still of serious proportions, have been reviewed by Nicholi and by Verebey and their associates.

**Cocaine**

The conventional use of cocaine as a local anesthetic has for many years been overshadowed by its illicit and widespread use as a stimulant and mood elevator. Originally, cocaine was sold as a white, lactose-adulterated powder that was administered intranasally (“snorted”); less often, it was smoked or injected intravenously or intramuscularly. Since 1985 there has been an alarming escalation in the use of cocaine, mainly because a relatively pure and inexpensive form of the free alkaloid base (“crack”) became readily available at that time. This form of cocaine is heat-stable and therefore suitable for smoking. According to the National Household Survey on Drug Abuse, there are an estimated 600,000 frequent cocaine users in the United States. (Frequent use was arbitrarily defined as use on 51 or more days during the preceding year.) The number of occasional users (less than 12 days in the preceding year) was 2.4 million. These figures are probably subject to significant underreporting.

A sense of well-being, euphoria, loquacity, and restlessness are the familiar effects. Pharmacologically, cocaine is thought to act like the tricyclic antidepressants; i.e., it blocks the presynaptic reuptake of biogenic amines, thus producing vasoconstriction, hypertension, and tachycardia and predisposing to generalized tremor, myoclonus, seizures, and psychotic behavior. These actions as well as its immediate mood-elevating and euphoric effects are much the same as those of dextroamphetamine (see earlier). The cocaine abuser readily develops psychologic dependence and habituation, i.e., an inability to abstain from frequent compulsive use (“craving”). The manifestations of physical dependence are more subtle and difficult to recognize. Nevertheless, abstinence from cocaine following a period of chronic abuse is regularly attended by insomnia, restlessness, anorexia, depression, hyperprolactinemia, and signs of dopaminergic hypersensitivity—a symptom complex that constitutes an identifiable withdrawal syndrome.

With the increasingly widespread use of cocaine, a variety of
new complications continues to emerge. The symptoms of severe intoxication (overdose), noted above, may lead to coma and death and require emergency treatment in an intensive care unit, along the lines indicated for the management of other forms of coma. Seizures often occur in this setting and are treated more effectively with benzodiazepines than with standard anticonvulsant drugs. Spontaneous subarachnoid or intracerebral hemorrhage and cerebral infarction have rarely followed the intranasal use and smoking of cocaine (Levine et al). These complications are presumably the result of vasospasm induced by the sympathomimetic actions of cocaine. Cocaine and amphetamines also, on occasion, produce a state of generalized vasospasm leading to multiple cortical infarctions and posterior white matter changes that are evident on imaging studies, not unlike those seen with hypertensive encephalopathy (page 728). Several cases of a pathologically verified vasculitis and instances of “beading” of cerebral vessels on the arteriogram have also been noted. We have seen several instances of vasospasm but have no experience with the vasculitis; however, it would seem that these two different types of vasculopathy can result from cocaine and amphetamine use (page 733). Roth and colleagues have described 39 patients who developed acute rhabdomyolysis after cocaine use; 13 of these had acute renal failure, severe liver dysfunction, and disseminated intravascular coagulation and 6 of them died. Some reports indicate that cocaine use during pregnancy may cause fetal damage, abortion, or persistent signs of toxicity in the newborn infant.

Anxiety, paranoia, and other manifestations of psychosis may develop within several hours of cocaine use. These complications are best treated with haloperidol.

Marijuana

During the past three decades the prevalence of marijuana use in the United States has declined by about half, but it is still the most commonly used illicit drug in the United States. The effects, when taken by inhaling the smoke from cigarettes or pipe, are prompt in onset and evanescent. With low doses, the symptoms are like those of mild alcohol intoxication (drowsiness, euphoria, dulling of the senses, and perceptual distortions). With increasing amounts, the effects are similar to those of LSD, mescaline, and psilocybin (see later); they may be quite disabling for many hours. With even larger doses, severe depression and stupor may occur, but death is rare (for a full account, see Hollister, 1988). No damage to the nervous system has been found after chronic use.

Reverse tolerance to marijuana (i.e., increasing sensitization) may be observed initially, but on continued use, tolerance to the euphoriant effects develops. In one of the few experimental studies of chronic marijuana use, the subjects reported feeling “jittery” during the first 24 h after abrupt cessation of smoking marijuana, although no objective withdrawal signs could be detected.

The mild antiepileptic and antinausea effect of marijuana coupled with euphoria have led to its use as an agent to ameliorate the effects of cancer chemotherapies, and this purported therapeutic effect is the mainstay of the movement for its legalization.

Mescaline, LSD, and Psilocybin

These drugs produce much the same clinical effects if given in comparable amounts. The perceptual changes are the most dramatic: the user describes vivid visual hallucinations, alterations in the shape and color of objects, unusual dreams, and feelings of depersonalization. An increase in auditory acuity has been described, but auditory hallucinations are rare. Cognitive functions are difficult to assess because of inattentiveness, drowsiness, and inability to cooperate in mental testing. The somatic symptoms consist of dizziness, nausea, paresthesias, and blurring of vision. Sympathomimetic effects—pupillary dilation, piloerection, hyperthermia, and tachycardia—are prominent, and the user may also show hyperreflexia, incoordination of the limbs, and ataxia.

Tolerance to LSD, mescaline, and psilocybin develops rapidly, even on a once-daily dosage. Furthermore, subjects tolerant to any one of these three drugs are cross-tolerant to the other two. Tolerance is lost rapidly when the drugs are discontinued abruptly, but no characteristic signs of physical dependence (abstinence syndrome) ensue. In this sense, addiction does not develop, although users may become dependent upon the drugs for emotional support (psychologic dependence or habituation).

Although LSD has no therapeutic value and the use of marijuana is governed by the federal narcotic laws, these drugs are taken by narcotic addicts as a substitute for more potent drugs, by “drugheads” (i.e., individuals who use any agent that alters consciousness), and by many troubled, unhappy college and high school students for social conformity or for reasons that even they cannot ascertain. Their use is attended by a number of serious adverse reactions taking the form of acute panic attacks, long-lasting psychotic states resembling paranoid schizophrenia, and flashbacks (spontaneous recurrences of the original LSD experience, sometimes precipitated by smoking marijuana and accompanied by panic attacks). Serious physical injury may follow upon impairment of the user’s critical faculties. Whether prolonged usage leads to permanent damage to the nervous system is uncertain; there are some data to suggest that this may happen, but there is little doubt that the mental state of some psychologically predisposed individuals is permanently altered. The reports claiming that LSD may cause chromosomal damage remain to be validated. Numerous claims have been made that LSD and related drugs are effective in the treatment of mental disease and a wide variety of social ills and that they have the capacity to increase one’s intellectual performance, creativity, and self-understanding. To date there have been no acceptable studies that validate any of these claims.

Phencyclidine (“Angel Dust”) and “Ecstasy”

During the early 1970s, the abuse of PCP and its analogues was a significant problem. The popularity of these drugs has dropped sharply, but some illicit use continues because they are relatively cheap, easily available, and quite potent. (Their manufacture as a veterinary anesthetic was stopped in 1979.) Phencyclidine is taken illicitly in the form of a granular powder, frequently mixed with other drugs, and is smoked or snorted. It is usually classified as a hallucinogen, although it also has stimulant and depressant properties. The effects of intoxication are like those of LSD and other hallucinogens and resemble those of an acute schizophrenic episode, which may last several days to a week or more. After the ingestion of a large amount (10 mg or more) of phencyclidine, it is present in the blood and urine for only a few hours.

Toxicity from the illicit use of “ecstasy” (NMDA) during all-night dance parties (“raves”) has increased as a result of its ill-founded reputation for safety. It appears to cause a release of both serotonin and dopamine in the brain and produces an elated state similar to the effects of cocaine. Seizures, cerebral hemorrhages, and psychosis have been reported in previously healthy individuals (Verebey et al).
A discussion of the legal implications of the illicit use of the aforementioned drugs and their social impact is beyond the scope of this chapter but can be found in the appended references.

**DISORDERS DUE TO BACTERIAL TOXINS**

The most important diseases in this category are *tetanus*, *botulism*, and *diphtheria*. Each is caused by an extraordinarily powerful bacterial toxin that acts primarily on the nervous system.

**Tetanus**

The cause of this disease is the anaerobic, spore-forming rod *Clostridium tetani*. The organisms are found in the feces of some humans and many animals, particularly horses, from which they readily contaminate the soil. The spores may remain dormant for many months or years, but when they are introduced into a wound, especially if a foreign body or supplicative bacteria are present, they are converted into their vegetative forms, which produce the exotoxin tetanospasmin. In developing countries, tetanus is still a common disease, particularly in newborns, in whom the spores are introduced via the umbilical cord (*tetanus neonatorum*). In the United States, the incidence rate of tetanus is about one per million per year. Injection of contaminated heroin is a significant cause.

About two-thirds of all injuries leading to tetanus occur from deep scratches and puncture wounds in the home and about 20 percent in gardens and on farms.

Since 1903, when Morax and Marie proposed their theory of centripetal migration of the tetanus toxin, it has been taught that spread to the nervous system occurs via the peripheral nerves, the toxin ascending in the axis cylinders or the perineural sheaths. Modern studies, utilizing fluorescein-labeled tetanus antitoxin, have disclosed that the toxin is also widely disseminated via blood or lymphatics, probably accounting for the generalized form of the disease. However, in local tetanus, the likely mode of spread to the CNS is indeed by retrograde axonal transport.

**Mode of Action of Tetanus Toxin**

Like botulinum toxin, the tetanus toxin is a zinc-dependent protease. It blocks neurotransmitter release by cleaving surface proteins of the synaptic vesicles, thus preventing the normal exocytosis of neurotransmitter. The toxin interferes with the function of the reflex arc by the blockade of inhibitory transmitters, mainly GABA, at presynaptic sites in the spinal cord and brainstem. Elicitation of the jaw jerk, for example, is normally followed by the abrupt suppression of motor neuron activity, manifested in the electromyogram (EMG) as a “silent period” (see further on). In the patient with tetanus, there is a failure of this inhibitory mechanism, with a resulting increase in activation of the neurons that innervate the masseter muscles (*trismus* or lockjaw). Of all neuromuscular systems, the masseter innervation seems to be the most sensitive to the toxin.

Not only do afferent stimuli produce an exaggerated effect, but also the motor neurons of the spinal cord and brainstem, there is evidence that the toxin acts directly on skeletal muscle at the point where the axon forms the end plate (accounting perhaps for localized tetanus) and also upon the cerebral cortex and the sympathetic nervous system, in the hypothalamus.

The incubation period varies greatly, from a day or two to a month or even longer. Long incubation periods are associated with mild and localized types of the disease.

**Clinical Features**

There are several clinical types of tetanus, usually designated as local, cephalic, and generalized.

**Generalized Tetanus**

This is the most common form. It may begin as local tetanus that becomes generalized after a few days, or it may be diffuse from the beginning. Trismus is frequently the first manifestation. In some cases this is preceded by a feeling of stiffness in the jaw or neck, slight fever, and other general symptoms of infection. The localized muscle stiffness and spasms spread quickly to other bulbar muscles as well as those of the neck, trunk, and limbs. A state of unrelenting rigidity develops in all the involved muscles: the abdomen is board-like, the legs are rigidly extended, and the lips are pursed or retracted (*risus sardonicus*); the eyes are partially closed by contraction of the orbicularis oculi, or the eyebrows are elevated by spasm of the frontalis. Superimposed on this persistent state of enhanced muscle activity are paroxysms of tonic contraction or spasm of muscles (tetanic seizures or convulsions), which occur spontaneously or in response to the slightest external stimulus. They are agonizingly painful. Consciousness is not lost during these paroxysms. The tonic contraction of groups of muscles results in opisthotonos or in forward flexion of the trunk, flexion and adduction of the arms, clenching of the fists, and extension of the legs. Spasms of the pharyngeal, laryngeal, or respiratory muscles carry the constant threat of apnea or suffocation. Fever and pneumonia are common complications. Large swings in blood pressure and pulse as well as profuse diaphoresis are typical, mainly in response to the intense muscular contractions but may also be related to the action of the toxin on the CNS. Death is usually attributable to asphyxia from laryngospasm, to heart failure, or to shock, the latter resulting from the action of the toxin on the hypothalamus and sympathetic nervous system.

Generalized spasms and rigidity of trunk and limbs developing in a neonate a few days after birth should always suggest the diagnosis of tetanus. This form of tetanus occurs when there has been inadequate sterile treatment of the umbilical cord stump in a neonate born to an unimmunized mother.

**Local Tetanus**

This is the most benign form. The initial symptoms are stiffness, tightness, and pain in the muscles in the neighborhood of a wound, followed by twitchings and brief spasms of the affected muscles. Local tetanus occurs most often in relation to a wound of the hand or forearm, rarely in the abdominal or paravertebral muscles. Gradually, some degree of continuous involuntar spasms becomes evident. This is referred to as rigidity, hypertonic contractions, or tetanic spasticity, terms that denote the sustained tautness of the affected muscles and resistance of the part to passive movement. Superimposed on this background of more or less continuous motor activity are brief, intense spasms, lasting from a few seconds to minutes and occurring “spontaneously” or in response to all variety of stimulation (Struppler and Adams). Early in the course of the illness there may be periods when the affected muscles are palpably soft and appear to be relaxed. A useful diagnostic maneuver at this stage is to have the patient perform some repetitive voluntary movements, such as opening and closing the hand, in response to which there occurs a gradual increase in the tonic contraction and spasms of the affected muscles, followed by spread to neighboring muscle groups (recruitment spasm). The phenomenon resembles paradoxical myotonia (page
Diphtheria, an acute infectious disease caused by Corynebacterium diphtheriae, is now quite rare in the United States and western Europe. The faucial-pharyngeal form of the disease, which is the most common clinical type, is characterized by the formation of an inflammatory exudate of the throat and trachea; at this site, the bacteria elaborate an exotoxin, which affects the heart and nervous system in about 20 percent of cases.

The involvement of the nervous system follows a predictable pattern (Fisher and Adams). It begins locally, with palatal paralysis (nasal voice, regurgitation, and dysphagia) between the fifth and twelfth days of illness. At this time or shortly afterward, other cranial nerves (trigeminal, facial, vagus, and hypoglossal) may also be affected. Ciliary paralysis with loss of accommodation and blurring of vision, but with preserved light reaction, appears usually in the second or third week. Rarely the extracranial muscles are weakened. The cranial nerve signs may clear without further involvement of the nervous system, or a delayed sensorimotor polyneuropathy may develop between the fifth and eighth weeks of the disease. The latter varies in severity from a mild, predominantly...
distal affection of the limbs to a rapidly evolving, ascending paralysis, like that of the Guillain-Barré syndrome; CSF findings are similar as well (acellular fluid with elevated protein). The neurologic symptoms progress for a week or two, and if the patient does not succumb to respiratory paralysis or cardiac failure (cardiomyopathy), these conditions stabilize and then improve slowly and more or less completely.

The early oropharyngeal symptoms, the unique ciliary paralysis with relatively retained pupillary response to light, and the subacute evolution of a delayed symmetrical sensorimotor peripheral neuropathy distinguish diphtheria from all other forms of polyneuropathy. The long latency between the initial infection and the involvement of the nervous system has no clear explanation. In experimental animals, Waksman and colleagues demonstrated that the toxin reaches the Schwann cells in the most vascular parts of the peripheral nervous system within 24 to 48 h of infection, but its metabolic effect on cell membranes extends over a period of weeks. As in humans, the toxin produces demyelination in the proximal parts of spinal nerves, in dorsal root ganglia, and in spinal roots. The cardiac musculature and the conducting system of the heart undergoes mild focal necrosis.

The source of diphtheritic infection may be extrafacial—a penetrating wound, skin ulcer, or umbilicus. The systemic and neurologic complications of faecal diphtheria can also be observed in the extrafacial form of the disease, after a similar latent period. It is probable, therefore, that the toxin reaches its neural site via the bloodstream; but, in addition, some action is exerted locally, as evidenced by palatal paralysis in faecal cases and by initial weakness and sensory impairment in the neighborhood of the infected wound.

There is no specific treatment for any of the neurologic complications of diphtheria. It is generally agreed that the administration of antitoxin within 48 h of the earliest symptoms of the primary diphtheritic infection lessens the incidence and severity of the peripheral nerve complications.

The polynervaopathy of diphtheria is discussed further in Chap. 46 (page 1128).

**Botulism**

Botulism is a rare form of food-borne illness caused by the exotoxin of *C. botulinum*. Outbreaks of poisoning are most often due to ingested bacteria contained in home-preserved than to commercially canned products, and vegetables and home-cured ham are incriminated more commonly than are other food products. Very rarely, a contaminated wound is the source of infection. Although the disease is ubiquitous, five western states (California, Washington, Colorado, New Mexico, and Oregon) account for more than half of all reported outbreaks in the United States. *Neonatal and infantile forms* of the disease have been reported. These are due to absorption of the toxin formed by germination of ingested spores (rather than ingestion of preformed toxin), an important source of which is contaminated natural (raw) honey. A few adult cases may have a similar source.

It is now well established, on the basis of observations in both animals and humans, that the primary site of action of botulinus toxin is at the neuromuscular junction, more specifically on the presynaptic endings. The toxin interferes with the release of acetylcholine from peripheral motor nerves by a mechanism like that of tetanus toxin on the spinal interneurons (see previous discussion). The physiologic defect is similar to the one that characterizes the myasthenic syndrome of Lambert-Eaton (page 1259) but different from that of myasthenia gravis.

Symptoms usually appear within 12 to 36 h of ingestion of the tainted food. Anorexia, nausea, and vomiting occur in most patients. As a rule, blurred vision and diplopia are the initial neural symptoms; their association with ptosis, strabismus, and extraocular muscle palsies, particularly of the sixth nerve, may at first suggest a diagnosis of myasthenia gravis. In botulism, however, the pupils are often unreactive. Other symptoms of bulbar involvement—nasality of the voice and hoarseness, dysarthria, dysphagia, and an inability to phonate—follow in quick succession, and these, in turn, are followed by progressive weakness of muscles of the face, neck, trunk, and limbs and by respiratory insufficiency. Despite the oropharyngeal weakness, it is not unusual for the gag reflex to be retained. Tendon reflexes are lost in cases of severe generalized weakness. These symptoms and signs evolve rapidly, over 2 to 4 days as a rule, and may be mistaken for those of the Guillain-Barré syndrome. Sensation remains intact, however, and the spinal fluid usually shows no abnormalities. Severe constipation is characteristic of botulism, due perhaps to paresis of smooth muscle of the intestine. Consciousness is retained throughout the illness unless severe degrees of anoxia develop. In the past, the mortality was consistently above 60 percent, but it has declined in recent decades, with improvements in the intensive care of acute respiratory failure and the effectiveness of *C. botulinum* antitoxins.

The clinical diagnosis can be confirmed by electrophysiologic studies. Specifically, there is reduced amplitude of evoked muscle potentials and an increase in amplitude with rapid repetitive nerve stimulation (the opposite of what is found in myasthenia gravis). In patients who recover, improvement begins within a few weeks, first in ocular movement, then in other cranial nerve function. Complete recovery of paralyzed limb and trunk musculature may take many months.

The three types of botulinus toxin, A, B, and E, cannot be distinguished by their clinical effects alone, so that the patient should receive the trivalent antiserum as soon as the clinical diagnosis is made. This antitoxin can be obtained from the Centers for Disease Control and Prevention, Atlanta. An initial dose of 10,000 U is given intravenously after intradermal testing for sensitivity to horse serum, followed by daily doses of 50,000 U intramuscularly until improvement begins.

Guanidine hydrochloride (50 mg/kg) has been somewhat useful in reversing the weakness of limb and extraocular muscles. Antitoxin and guanidine probably change the course of the illness relatively little, and recovery, in the final analysis, depends on the effectiveness of respiratory care, maintenance of fluid and electrolyte balance, prevention of infection, and so on.

The skilled injection of small quantities of botulinus toxin into a muscle will weaken or paralyze it for weeks to months. Advantage is taken of this phenomenon in the treatment of the localized dystonias (page 93).

**POISONING DUE TO PLANTS, VENOMS, BITES, AND STINGS**

**Ergotism**

Ergotism is the name applied to poisoning with ergot, a drug derived from the rye fungus *Claviceps purpurea*. Ergot is used therapeutically to control postpartum hemorrhage due to uterine atony; one of its alkaloids, ergotamine, is used in the treatment of
migraine, and a class of dopamine agonists used in the treatment of Parkinson disease has ergot activity. Chronic overdosage of the drug is the usual cause of ergotism; acute overdosage in the post-partum state or in the treatment of migraine may cause an alarming rise in blood pressure.

Two types of ergotism are recognized: gangrenous, due to a vasospastic, occlusive process in the small arteries of the extremities, and convulsive, or neurogenic ergotism. The latter is characterized by fasciculations, myoclonus, and spasms of muscles, followed by seizures. In nonfatal cases, a tabes-like neurologic syndrome may develop, with loss of knee and ankle jerks, ataxia, and impairment of deep and superficial sensation. The pathologic changes are said to consist of degeneration of the posterior columns, dorsal roots, and peripheral nerves, but they have been poorly described. The relation of these changes to ergot poisoning is not clear, since most of the cases have occurred in areas where malnutrition was endemic. The authors have had no experience with this condition.

**Lathyrisim**

*Lathyrisim* is a neurologic syndrome characterized by the relatively acute onset of pain, paresthesias, and weakness in the lower extremities, progressing to a permanent spastic paraplegia. It is a serious medical problem in India and in some North African countries and is probably due to a toxin contained in the chickling vetch, *Lathyria*, a legume that is consumed in excess quantities during periods of famine. This disorder is discussed further with the spinal cord diseases (page 1083).

**Mushroom Poisoning**

The gathering of wild mushrooms, a popular pastime in late summer and early fall, always carries with it the danger of poisoning. As many as 100 species of mushrooms are poisonous. Most of them cause only transient gastrointestinal symptoms, but some elaborate toxins that can be fatal. The most important of these toxins are the cyclopeptides, which are contained in several species of *Amanita phalloides* and *muscaria* and account for more than 90 percent of fatal mushroom poisonings. These toxins disrupt RNA metabolism, causing hepatic and renal necrosis. Symptoms of poisoning with *Amanita* usually appear between 10 and 14 h after ingestion and consist of nausea, vomiting, colicky pain, and diarrhea, followed by irritability, restlessness, ataxia, hallucinations, convulsions, and coma. There may be added evidence of a polymyopathy presenting as flaccid areflexic paralysis, high serum CK, diminished EMG potentials, and fiber necrosis.

Other important toxins are methylhydrazine (contained in the *cyromitra* species) and muscarine (*inocybe* and *clitocybe* species). The former gives rise to a clinical picture much like that caused by the cyclopeptides. The symptoms of muscarine poisoning, which appear within 30 to 60 min of ingestion, are essentially those of parasymptomatic stimulation—miosis, lacrimation, salivation, nausea, vomiting, diarrhea, perspiration, bradycardia, and hypotension. Tremor, seizures, and delirium occur in cases of severe poisoning.

The mushroom toxins have no effective antidotes. If vomiting has not occurred, it should be induced with ipecac, following which activated charcoal should be administered orally in order to bind what toxin remains in the gastrointestinal tract. A local poison control center may help identify the poisonous mushroom and its toxin. Even more important, the gathering and ingestion of field varieties of mushrooms should be left to those absolutely certain of their identity.

**Buckthorn Poisoning**

A rapidly progressive and sometimes fatal paralysis follows the ingestion of the small fruit of the buckthorn shrub that is indigenous to northern Mexico and the neighboring southwestern parts of the United States. The responsible toxin causes a predominantly motor polyneuropathy, probably of axonal type. Except for a normal spinal fluid protein concentration, the disorder closely resembles Guillian-Barré syndrome and tick paralysis (see below), and its recognition depends on awareness of ingestion of the fruit in endemic areas.

**Neurotoxin Fish Poisoning (Ciguatera)**

Ingestion of marine toxins that block neural sodium channels is a common form of poisoning throughout coastal areas and islands of the world. It results from eating fish that have fed on toxin-containing microscopic dinoflagellates. Reef fish and shellfish are exposed to high concentrations of these organisms during periodic upswings in the population of the dinoflagellates. They may be so profuse as to color the surrounding water (red tide). Although the toxins differ (tetrodotoxin—pufferfish; ciguatoxin—snails; saxitoxin and brevitoxin—shellfish), the neurologic and gastrointestinal symptoms that follow the ingestion of poisoned fish are similar. The initial symptoms are diarrhea, vomiting, or abdominal cramps coming on minutes to hours after the ingestion. These are followed by paresthesias that begin periorally and then involve the limbs distally. Hot and cold sensory stimuli (e.g., ice cream) are characteristically associated with electrical-like or burning paresthesias. Muscle aches and shooting pains are also mentioned by most patients. In pufferfish poisoning and in advanced stages of poisoning from other fish, weakness occurs, and there have been a few reports of coma and of respiratory failure. The recognition of this type of fish poisoning is straightforward in endemic areas, in some of which there is a seasonal clustering of cases. In tourists returning home from endemic areas or in persons consuming imported fish, the illness may be mistaken for the Guillian-Barré syndrome. Prominent perioral paresthesias should suggest the correct diagnosis. Supportive treatment is all that is required, but treatment with intravenous mannitol is said to hasten recovery.

Pearn reviews the biochemistry and physiologic and clinical effects of the various marine toxins and points out a form of chronic intoxication unknown to us but apparently endemic in certain island communities. The ostensible main chronic effects are severe fatigue and asthenic weakness. The problem of distinguishing this syndrome from depression is acknowledged by the author and the cases on which we have consulted locally almost always fall into the psychiatric category.

**Venoms, Bites, and Stings**

These are relatively rare but nonetheless important causes of mortality in the United States. The venoms of certain species of snakes, lizards, spiders (especially the black widow spider, page 1280), and scorpions contain neurotoxins that may cause a fatal depression of respiration and curare-like paralysis of neuromuscular transmission. In the United States, there are about 8000 poisonous snake bites per year. Some, such as the coral snake envenomation, are...
neurotoxic, producing pupillary dilatation, ptosis, ocular palsies, ataxia, and respiratory paralysis. Others (rattlesnakes, water moccasin snakes) cause tissue necrosis and circulatory collapse. These are reviewed by Gold and colleagues. The serious effects of *Hypermegoptera stings* (bees, wasps, hornets, and fire ants) are due mainly to hypersensitivity and anaphylaxis. Several instances of cerebral or myocardial infarction have been reported after bee and wasp stings (Crawley et al). All of these disorders are discussed in detail in *Harrison’s Principles of Internal Medicine*.

**Tick Paralysis**

This rare condition is the result of a toxin secreted by the gravid tick. In Canada and the northeastern United States, the wood tick *Dermacentor andersoni* is mainly responsible; in the southeastern United States it is *Dermacentor variabilis*, a dog tick (the tick in Australia is the *Ixodes holocyclus*), but various other ticks may occasionally have the same effect. The illness is more common and is generally more severe in cases on the Australian Continent than it is in North America. Most cases occur in children because their small body mass renders them susceptible to the effects of relatively small amounts of the toxin. The illness arises almost exclusively in the spring, when the mature gravid ticks are most plentiful. Clinical manifestations require that the tick be attached to the skin for several days.

The neurotoxin causes a generalized, flaccid, areflexic paralysis, appearing over 1 or 2 days thereby mimicking the Guillain-Barré syndrome. In a few cases, several days of ataxia and areflexia precede the paralysis, but sensory loss tends to be minimal. External ophthalmoplegia, which occurred in 5 of the 6 children described by Grattan-Smith et al, is exceptional judging by other reports; internal ophthalmoplegia and pharyngeal weakness are also known to occur, and while not typical, raise the possibility of botulism or diphtheria. The CSF is normal and electrophysiologic potentials but normal or only slightly slowed nerve conduction. Prominent ptosis and neck weakness may also raise the question of a neuromuscular process, but repetitive stimulation testing is normal or evokes only a slight decrement or increment in some cases.

The ticks tend to attach to the hairlines or in the matted hair of the scalp, neck, and pubis, where a careful search will reveal them (for which reason nurses and electroencephalography technicians often are most likely to find them; see Felz et al). The diagnosis is much in the awareness of clinicians in endemic areas during the tick season, for they are gratified with rapid and dramatic improvement when the tick is removed. The paralysis is reported to become transiently worse after tick removal in some of the Australian cases.

From a neurologic point of view, the frequent disorder that follows tick bite is what has come to be known as *Lyme disease*—so named for the Connecticut community in which it was discovered. The causative agent is *Borrelia burgdorferi*, a spirochetal organism. The disorder is discussed fully with other infectious diseases in Chap. 32 and in Chap. 46, with the neuropathies.

**HEAVY METALS**

**Lead**

The causes and clinical manifestations of lead poisoning are quite different in children and adults.

**Lead Poisoning in Children**

In the United States, this disease has been identified most often in 1- to 3-year-old children who inhabit urban slum areas where old, deteriorated housing prevails. (Lead paint was used in most houses built before 1940 and in many built before 1960.) The chewing of leaded paint is promoted by compulsive ingestion (pica) from windowills and painted plaster walls. The development of an acute encephalopathy is the most serious complication, resulting in death in 5 to 20 percent of cases and in permanent neurologic and mental deficits in more than 25 percent of survivors.

**Clinical Manifestations** These develop over a period of 3 to 6 weeks. The child becomes anorectic, less playful and less alert, and more irritable. These symptoms may be misinterpreted as a behavior disorder or a manifestation of mental retardation. Intermittent vomiting, vague abdominal pain, clumsiness, and ataxia may be added. If these early signs of intoxication are not recognized and the child continues to ingest lead, more flagrant signs of acute encephalopathy may develop—most frequently in the summer months, for reasons that are not understood. Vomiting becomes more persistent, apathy progresses to drowsiness and stupor interspersed with periods of hyperirritability, and finally, seizures and coma supervene. This syndrome may evolve in a period of a week or less, most rapidly in children under 2 years of age; in older children, it is more likely to develop in recurrent and less severe episodes. This clinical syndrome must be distinguished from tuberculous meningitis, viral meningoencephalitis, and the various conditions causing acute increased intracranial pressure. Usually, in lead encephalopathy, the CSF is under increased pressure with manifest papilledema, and there may be a slight lymphocytic pleocytosis and elevated protein, but normal glucose values. It follows that lumbar puncture should be done with caution and only if it is essential for diagnosis.

**Diagnosis** Since the symptoms of plumbism are nonspecific, the diagnosis depends on an appreciation of the causative factors, a high index of suspicion, and the results of certain laboratory tests. The presence of lead lines at the metaphyses of long bones and basophilic stippling of red cells are too inconstant to be relied on, but basophilic stippling of bone marrow normoblasts is uniformly increased. Impairment of heme synthesis, which is exquisitely sensitive to the toxic effects of lead, results in the increased excretion of urinary coproporphyrin (UCP) and of δ-aminolevulinic acid (ALA). These urinary indices and the lead concentrations in the serum bear an imperfect relationship to the clinical manifestations. In the test for UCP, which is readily performed in the clinic and emergency department, a few milliliters of urine are acidified with manifest papilledema, and there may be a slight lymphocytic pleocytosis and elevated protein, but normal glucose values. It follows that lumbar puncture should be done with caution and only if it is essential for diagnosis.

**Pathology** In children who die of acute lead encephalopathy, the brain is massively swollen, with herniation of the temporal lobes
and cerebellum, multiple microscopic ischemic foci in the cerebrum and cerebellum, and endothelial damage and deposition of proteinaceous material and mononuclear inflammatory cells around many of the small blood vessels. There are also hyperplastic changes in arteries and arterioles, and in some places, perivascular infiltrates of lymphocytes and mononuclear cells. In the territories of some of these vessels there are foci of ischemic necrosis with surrounding glial reaction appropriate for the age of the lesion. Similar changes are present in the kidney.

At blood lead concentrations of 70 mg/dL symptoms may be minimal, but acute encephalopathy may occur abruptly and unpredictably, for which reason the child should be hospitalized for chelation therapy. Some children with a blood lead level of 50 mg/dL may have symptoms of severe encephalopathy, whereas others may be asymptomatic. In the latter case, an attempt should be made to discover and remove the source of lead intoxication and the child should be reexamined at frequent intervals. The seriousness of lead encephalopathy is indicated by the fact that most of the children who become stuporous or comatose remain mentally retarded despite treatment. The physician’s aim, therefore, is to institute treatment before the severe symptoms of encephalopathy have become manifest.

**Treatment** The plan of therapy includes the following:

1. Establishment of urinary flow, following which intravenous fluid therapy is restricted to basal water and electrolyte requirements.
2. In cases of acute encephalopathy, combined chelation therapy with 2,3-dimercaptopropanol (BAL, 12 to 24 mg/kg) and CaNa₂ EDTA (0.5 to 1.5 g/m² body surface area) for 5 to 7 days. This is followed by a course of oral penicillamine (40 mg/kg, not exceeding 1 g/day). In acute cases the goal is to reduce the serum lead levels below 40 mg/dL. Once the absorption of lead has ceased, chelating agents remove lead only from soft tissues and not from bone, where most of the lead is stored. Any intercurrent illness may result in a further mobilization of lead from bones and soft tissues and an exacerbation of symptoms of lead intoxication.
3. Repeated doses of mannitol for relief of cerebral edema.
4. Microcytic hypochromic anemia is treated with iron once the chelating agents have been discontinued.
5. Seizures are best controlled with intravenous diazepam or midazolam.

**Prevention** The prevention of retoxication (or initial intoxication) demands that the child be removed from the source of lead. Although this is axiomatic, it is often difficult to accomplish, despite the best efforts of local health departments and hospital and city social workers. Nevertheless, an attempt to eliminate the environmental factor must be made in each case. Such attempts, among other things, have resulted in a marked decrease in the incidence of acute lead encephalopathy in the past two decades. Although florid examples of this encephalopathy are now uncommon, undue exposure to lead (blood levels > 30 mg/dL) remains inordinately prevalent and a continuing source of concern to public health authorities. As to the levels that pose a danger to the child, there is still some uncertainty. Rutter, who reviewed all of the evidence up to 1980, concluded that persistent blood levels above 40 mg/dL may cause slight cognitive impairment and, less certainly, an increased risk of behavioral difficulties. More recently, Canfield and colleagues have reported, from a prospective study of 172 children, that even lower levels may induce a decline in IQ at 3 and 5 years of age. These data require confirmation before general acceptance. Further compounding the problem of interpreting low-level lead exposure in children with blood lead concentrations below 45 g/dL is the observation by Rogan and colleagues that treatment with succimer, while successful in reducing lead levels, did not improve cognitive or behavioral function. The oral lead chelator succimer is approved for outpatient treatment of asymptomatic children with blood lead levels higher than 45 mg/dL. A 3-week course of treatment is given, with weekly monitoring of blood lead levels to identify lead mobilization from bones and soft tissues (Jorgensen).

In 1988, on the basis of epidemiologic and experimental studies in the United States, Europe, and Australia, the Agency for Toxic Substances and Disease Registry set a much lower threshold for neurobehavioral toxicity (10 to 15 mg/dL). They estimated that 3 to 4 million American children have blood levels in excess of this amount. Needleman et al studied the long-term effects of low doses of lead in asymptomatic children, 132 of whom had had demonstrable levels of lead in the dentin of shed teeth (average 24 mg/dL). Eleven years later, the children were found to have behavioral abnormalities proportionate to their early lead levels. In comparison to a normal population, more had dropped out of school and more had lower vocabulary and grammatical reasoning scores, more reading difficulty, poorer hand-eye coordination performance, slower finger-tapping rates, and longer reaction times. The authors claimed to have eliminated other confounding variables such as lower social class and genetic factors. These findings are similar to those of the long-term studies of Baghurst et al (see also Mahaffey). There are no adequate pathologic or MRI studies of such cases.

**Lead Intoxication in Adults** Lead intoxication in adults is much less common than in children. The hazards to adults are the result of inhaling the dust of inorganic lead salts and the fumes from the burning of objects containing lead or involvement in processes that require the remelting of lead. Painting, printing, pottery glazing, lead smelting, welding, and storage battery manufacturing are the industries in which these hazards are most risky to occur. In the past, miners and brass foundry and garage workers (during automobile radiator repair, when soldered joints were heated) were the ones most at risk. Currently, other, sometimes idiosyncratic, sources are more common. For example, the authors have encountered a striking case of lead encephalopathy in a man of Indian origin who was taking large amounts of an Ayurvedic herbal remedy for arthritis. The first manifestation was a series of generalized seizures followed by a fluctuating encephalopathy. His serum lead level was 70 mg/dL, and 24-h urine collection contained 1550 mg of lead (normal being < 400 mg). There was a T2-weighted hyperintensity in the cerebral cortex. Whitfield and colleagues reviewed 23 instances of lead encephalopathy in adults. At the time of their report most cases were due to moonshine (homemade whiskey from lead-lined stills). More recently most cases have been from various herbal medications as already mentioned. Combined lead and arsenic poisoning from herbal compounds is also known.

The usual manifestations of lead poisoning in adults are colic, anemia, and peripheral neuropathy. Encephalopathy of the type described above is decidedly rare. Lead colic, frequently precipitated by an intercurrent infection or by alcohol intoxication, is characterized by severe, poorly localized abdominal pain, often with rigidity of abdominal muscles but without fever or leukocytosis. The
pain responds to the intravenous injection of calcium salts, at least temporarily, but responds poorly to morphine. Mild anemia is common. A black line of lead sulfide may develop along the gingival margins. Peripheral neuropathy, usually a bilateral wrist drop, is a rare manifestation and is discussed on page 1132.

The diagnostic tests for plumblism in children are generally applicable to adults, with the exception of bone films, which are of no value in the latter. Also, the treatment of adults with chelating agents follows the same principles as in children.

Intoxication with tetraethyl and tetramethyl (organic) lead, used as additives in gasoline, is caused by inhalation of gasoline fumes. It occurs most often in workers who clean gasoline storage tanks. Insomnia, irritability, delusions, and hallucinations are the usual clinical manifestations, and a manicat state may develop. The hematologic abnormalities of inorganic lead poisoning are not found, and chelating agents are of no value in treatment. Organic lead poisoning is usually reversible, but fatalities have been reported. The pathologic changes have not been well described.

Arsenic

In the past, medications such as Fowler’s solution (potassium arsenite) and the arsphenamines, used in the treatment of syphilis, were frequent causes of intoxication, but now the most common cause is the suicidal or accidental ingestion of herbicides, insecticides, or rodenticides containing copper acetarsenate (Paris green) or calcium or lead arsenate. In rural areas, arsenic-containing insecticide sprays are a common source of poisoning. Arsenic is used also in the manufacture of paints, enamels, and metals; as a disinfectant for skins and furs; and also in galvanizing, soldering, etching, and lead plating. Occasional cases of poisoning are reported in relation to these occupations. Arsenic is still contained in some topical creams and oral solutions that are used in the treatment of psoriasis and other skin disorders and in some herbal remedies.

Arsenic exerts its toxic effects by reacting with the sulfhydryl radicals of certain enzymes necessary for cellular metabolism. The effects on the nervous system are those of an encephalopathy or peripheral neuropathy. The latter may be the product of chronic poisoning or may become manifest between 1 and 2 weeks after recovery from the effects of acute poisoning. It takes the form of a distal axonopathy that is described on page 1132. In cases of arsenical polyneuropathy we have cared for, a distal sensorimotor areflexic syndrome developed subacutely. At autopsy there was a dying back pattern of myelin and axons with macrophage and Schwann cell reactions and chromatolysis of motor neurons and sensory ganglion cells. The CNS appeared normal.

The symptoms of encephalopathy (headache, drowsiness, mental confusion, delirium, and convulsive seizures) may also occur as part of acute or chronic intoxication. In the latter case, they are accompanied by weakness and muscular aching, hemolysis, chills and fever, mucosal irritation (in patients exposed to arsine gas), diffuse scaly desquamation, and transverse white lines, 1 to 2 mm in width, above the lunula of each fingernail (Mees lines). Acute poisoning by the oral route is associated with severe gastrointestinal symptoms, circulatory collapse, and death in a large proportion of patients. The CSF is normal. Examination of the brain in such cases discloses myriads of punctate hemorrhages in the white matter. Microscopically, the lesions consist of capillary necrosis and of pericapillary zones of degeneration, which, in turn, are ringed by red cells (brain purpura or encephalorrhagia, incorrectly referred to as hemorrhagic encephalitis). These neuropathologic changes are not specific for arsenical poisoning but have been observed in such diverse conditions as pneumonia, gram-negative bacillary septicemia from urinary tract infections, sulfonamide and phosgene poisoning, dysentery, disseminated intravascular coagulation, and others.

The diagnosis of arsenical poisoning depends on the demonstration of increased levels of arsenic in the hair and urine. Arsenic is deposited in the hair within 2 weeks of exposure and may remain fixed there for long periods. Concentrations of more than 0.1 mg arsenic per 100 mg hair are indicative of poisoning. Arsenic also remains within bones for long periods and is slowly excreted in the urine and feces. Excretion of more than 0.1 mg arsenic per liter of urine is considered abnormal; levels greater than 1 mg/L may occur soon after acute exposure. We would caution, however, that individuals who consume fish on a regular basis, as occurs in our coastal region of the country, may have slightly or moderately elevated levels of arsenic and that various conditions such as neuropathy and amyotrophic lateral sclerosis (ALS) may be mistakenly attributed to this innocuous finding. The levels return to normal within a few months of abstaining from fish.

The CSF protein level may be raised (50 to 100 mg/dL).

**Treatment** Acute poisoning is treated by gastric lavage, vasoconstrictor agents, dimercaprol (BAL), maintenance of renal perfusion, and exchange transfusions if massive hemoglobinuria occurs. Once polyneuropathy has occurred, it is little affected by treatment with BAL, but other manifestations of chronic arsenical poisoning respond favorably. There has been a gradual recovery from the polyneuropathy under our care.

Manganese

Manganese poisoning results from the chronic inhalation and ingestion of manganese particles and occurs in miners of manganese ore and in workers who separate manganese from other ore. Several clinical syndromes have been observed. The initial stages of intoxication may be marked by a prolonged confusional-hallucinatory state. Later, the symptoms are predominantly extrapyramidal. They are often described as parkinsonian in type, but in the patients seen by the authors, the resemblance was not close: an odd gait (“cock” walk), dystonia and rigidity of the trunk, postural instability, and falling backward were features seen in two South American miners. Others, however, have reported stiffness and awkwardness of the limbs, often with tremor of the hands, “cogwheel” phenomenon, gross rhythmic movements of the trunk and head, and retropulsive and propulsive gait. Corticospinal and corticobulbar signs may be added. Progressive weakness, fatigability, and sleepiness as well as psychiatric symptoms (manganese madness) are other clinical features. Rarely, severe axial rigidity and dystonia, like those of Wilson disease, are said to have been the outstanding manifestations.

Neuronal loss and gliosis, affecting mainly the pallidum and striatum but also the frontoparietal and cerebellar cortex and hypothalamus, have been described, but the pathologic changes have not been carefully studied.

**Treatment** The neurologic abnormalities have not responded to treatment with chelating agents. In the chronic dystonic form of manganese intoxication, dramatic and sustained improvement has been reported with the administration of L-dopa; patients with the more common parkinsonian type of manganese intoxication have shown only slight if any improvement with L-dopa.
Mercury poisoning arises in two forms, one due to inorganic compounds (elemental or mercury salt) and the other, more dangerous, to organic mercury. The sources of potential exposure are reviewed by Clarkson and colleagues. Among the organic compounds, methyl mercury gives rise to a wide array of serious neurologic symptoms that may be delayed for days or weeks after exposure, including tremor of the extremities, tongue, and lips; mental confusion; and a progressive cerebellar syndrome, with ataxia of gait and arms, intention tremor, and dysarthria. Choreaathetosis and parkinsonian facies have also been described. Changes in mood and behavior are prominent, consisting at first of subjective weakness and fatigability and later of extreme depression and lethargy alternating with irritability. This delayed form of subacute mercury poisoning has been reported in chemical laboratory workers after exposure to methyl mercury compounds. These agents, particularly dimethyl mercury, are extremely hazardous because they are absorbed transdermally and by inhalation, allowing severe toxicity to occur with even brief contact. In a fatal case of a chemist reported by Nierenberg et al., a rapidly progressive ataxia and stupor progressing to coma developed 154 days after exposure. Cerebellar function was most severely impaired, and visual function was affected.

The pathologic changes are characterized by a striking degeneration of the granular layer of the cerebellar cortex, with relative sparing of the Purkinje cells and neuronal loss and gliosis of the calcarine cortex and to a lesser extent of other parts of the cerebral cortex similar to the Minamata cases described later.

The chronic form of inorganic mercury poisoning occurs in persons exposed to large amounts of the metal used in the manufacture of thermometers, mirrors, incandescent lights, x-ray machines, and vacuum pumps. Since mercury volatilizes at room temperature, it readily contaminates the air and then condenses on the skin and respiratory mucous membranes. Nitrate of mercury, used formerly in the manufacture of felt hats (“mad hatters”), and phenyl mercury, used in the paper, pulp, and electrochemical industries, are other sources of intoxication. Paresthesias, lassitude, confusion, incoordination, and intention tremor are characteristic, and, with continued exposure, a delirious state occurs. Headache, various bodily pains, visual and hearing disorders, and corticospinal signs may be added, but their pathologic basis is unknown. The term erethism was coined to describe the timidity, memory loss, and insomnia that were said to be characteristic of chronic intoxication. If the exposure is more than a minimal degree over a long period, gastrointestinal disturbances are prone to occur (anorexia, weight loss), as well as stomatitis and gingivitis with loosening of the teeth. Acute exposure to inorganic mercury in larger amounts is more corrosive to the gastrointestinal system and produces nausea, vomiting, hematemesis, abdominal pain, and bloody diarrhea as well as renal tubular necrosis.

Isolated instances of polyneuropathy associated with exposure to mercury have also been reported (Albers et al, Agocs et al) and may be responsible for the paresthesias that accompany most cases as well as the acrodynia syndrome described below. The polyneuropathy associated with mercury poisoning is discussed on pages 1130 and 1132. The inhalation of vaporized mercury as a result of extensive dental work, or simply the presence of a large number of fillings (“amalgam illness”), is alleged to affect the peripheral nerves or to cause fatigue, but the connection is highly doubtful.

The presence of mercury in industrial waste has contaminated many sources of water supply and fish, which are ingested by humans and cause mercurial poisoning. So-called Minamata disease is a case in point. Between 1953 and 1956, a large number of villagers living near Minamata Bay in Kyushu Island, Japan, were afflicted with a syndrome of chronic mercurialism, traced to the ingestion of fish that had been contaminated with industrial wastes containing methyl mercury. Concentric constriction of the visual fields, hearing loss, cerebellar ataxia, postural and action tremors, and sensory impairment of the legs and arms and sometimes of the tongue and lips were the usual clinical manifestations. The syndrome evolved over a few weeks. Pathologically there was diffuse neuronal loss in both cerebral and cerebellar cortices, most marked in the anterior parts of the calcarine cortex and granule cell layer of the cerebellum. CT scans in survivors, years after the mass poisoning, disclosed bilaterally symmetrical areas of decreased attenuation in the visual cortex and diffuse atrophy of the cerebellar hemispheres and vermis, especially the inferior vermis (Tokuumi et al).

A painful neuropathy of children (acrodynia) has been traced to mercury exposure from interior latex paint, to calomel (mercurous chloride), to teething powders, and to a mercuric fungicide used in washing diapers (Agocs et al, Clarkson). Albers and colleagues observed the appearance of symptoms (mild decrease in strength, tremor, and incoordination) 20 to 35 years after exposure to elemental mercury. These authors believed that the natural neuronal attrition with aging had unmasked the neurologic disorder, a theory which we cannot validate.

Treatment In the treatment of chronic mercury poisoning, penicillamine has been the drug of choice, since it can be administered orally and appears to chelate mercury selectively, with less effect on copper, which is an essential element in many metabolic processes. Dimercaptosuccinic acid (succimer), which is also given orally and has few side effects, will probably prove to be a superior form of treatment (Clarkson). Because it increases the concentration of mercury in the brain, BAL is an unsuitable chelating agent.

Phosphorus and Organophosphate Poisoning

Nervous system function may be deranged as part of acute and frequently fatal poisoning with inorganic phosphorus compounds (found in rat poisons, roach powders, and match heads). More important clinically is poisoning with organophosphorus compounds, the best known of which is triorthocresyl phosphate (TOCP).

Organophosphates are widely used as insecticides. Since 1945, approximately 15,000 individual compounds in this category have come into use. Certain ones, such as tetraethylpyrophosphate, have been the cause of major outbreaks of neurologic disorder, especially in children. These substances have an acute anticholinesterase effect but no delayed neurotoxic action. Chlorophos, which is a 1-hydroxy-2,2,2-trichloroethylphosphonate, is an exception; it has both an acute and delayed action, as does TOCP.

The immediate anticholinesterase effect manifests itself by headache, vomiting, sweating, abdominal cramps, salivation, wheezing (secondary to bronchial spasm), miosis, and muscular weakness and twitching. Most of these symptoms can be reversed by administration of atropine and pralidoxine. The delayed effect manifests 2 to 5 weeks following acute organophosphorus insecticide poisoning. This takes the form of a distal symmetrical sensorimotor (predominantly motor) polyneuropathy, progressing to muscle atrophy (see Chap. 46). Recovery occurs to a variable degree, and then, in patients poisoned with TOCP, signs of cortico-
spinal damage become detectable. The severity of paralysis and its permanence vary with the dosage of TOCP. Whether a polyneuropathy can arise without the preceding symptoms of cholinergic toxicity is debated; however, based on a review of the subject and a study of 11 patients exposed to these agents, 3 of whom later acquired sensory neuropathy, Moretto and Lotti express the view that such an occurrence must be rare.

In addition to the acute and delayed neurotoxic effects of organophosphorus, an intermediate syndrome has been described (Senanayake and Karalliedde). Symptoms come on 24 to 96 h after the acute cholinergic phase and consist of weakness or paralysis of proximal limb muscles, neck flexors, motor cranial nerves, and respiratory muscles. Respiratory paralysis may prove fatal. In patients who survive, the paralytic symptoms last for 2 to 3 weeks and then subside. The intermediate and delayed symptoms do not respond to atropine or other drugs.

Several striking outbreaks of TOCP poisoning have been reported. During the latter part of the prohibition era and to a lesser extent thereafter, outbreaks of so-called jake paralysis were traced to drinking an extract of Jamaica ginger that had been contaminated with TOCP. Adams had examined several “ginger jake” patients many years later and related to us that he found only signs of corticospinal disease. Presumably in the early stage of this disease they were obscured by the neuropathy. Another outbreak occurred in Morocco, in 1959, when lubricating oil containing TOCP was used deliberately to dilute olive oil. Several other outbreaks have been caused by the ingestion of grain and cooking oil that had been stored in inadequately cleaned containers previously used for storing TOCP.

The effect of TOCP on the peripheral nervous system has been studied extensively in experimental animals. In cats, there occurs a dying back from the terminal ends of the largest and longest medullated motor nerve fibers, including those from the annulospiral endings of the muscle spindles (Cavanagh and Patangia). The long fiber tracts of the spinal cord show a similar dying-back phenomenon. Abnormal membrane-bound vesicles and tubules were observed by Prineas to accumulate in axoplasm before degeneration. These effects have been traced to the inhibitory action of TOCP on esterases. There is still uncertainty as to the details of these reactions, and no treatment for the prevention or control of the neurotoxic effects has been devised.

Thallium

In the late nineteenth century, thallium was used medicinally in the treatment of venereal disease, ringworm, and tuberculosis and later in rodenticides and insecticides. Poisoning was fairly common. Sporadic instances of poisoning still occur, usually as a result of accidental or suicidal ingestion of thallium-containing rodenticides and rarely from overuse of thallium-containing depilatory agents. Patients who survive the effects of acute poisoning develop a rapidly progressive and painful sensory polyneuropathy, optic atrophy, and occasionally ophthalmoplegia—followed, 15 to 30 days after ingestion, by diffuse alopecia (see page 1130). The latter feature should always suggest the diagnosis of thallium poisoning, which can be confirmed by finding this metallic element in the urine. Two of our patients had a severe sensory and mild motor polyneuropathy and alopecia, from which they were recovering months later. It is not uncommon for the neuropathy to have a painful component involving aural regions. The condition can end fatally. The use of potassium chloride by mouth may hasten thallium excretion.

Other Metals

Iron, antimony, tin, aluminum, zinc, barium, bismuth, copper, silver, gold, platinum, and lithium may all produce serious degrees of intoxication. The major manifestations in each case are gastrointestinal or renal, but certain neurologic symptoms—notably headache, irritability, confusional psychosis, stupor, coma, and convulsions—may be observed in any of these if the poisoning is severe, often as a terminal event.

Gold preparations, which are still used occasionally in the treatment of arthritis, may, after several months of treatment, give rise to focal or generalized myokymia and a rapidly progressive, symmetrical polyneuropathy (Katrak et al). The adverse effects of platinum are discussed later, with the antineoplastic agents. Lithium has been discussed earlier.

Attention has already been drawn to the possible causative role of aluminum intoxication in so-called dialysis dementia or encephalopathy (page 971). Removal of aluminum from the water used in renal dialysis has practically eliminated this disorder. It should be noted that the neuropathologic changes in experimental aluminum intoxication (see later) are not those observed in dialysis dementia. Perl and colleagues have reported the accumulation of aluminum in tangle-bearing neurons of patients with Alzheimer disease and in the Guamanian Parkinson–dementia–ALS complex. However, analysis of neuritic plaques by nuclear microscopy, without using chemical stains, failed to demonstrate the presence of aluminum (Landsberg et al). The significance of these findings remains to be determined. Longstreth and colleagues have described a progressive neurologic disorder consisting of intention tremor, incoordination, and spastic paraparesis in three patients who had worked for more than 12 years in the same pot room of an aluminum smelting plant. Similar cases clearly attributable to aluminum intoxication have not been reported, however.

Organic compounds of tin may seriously damage the nervous system. Diffuse edema of the white matter of the brain and spinal cord has been produced experimentally with triethyltin. Presumably this was the basis of the mass poisoning produced by a triethyltin-contaminated drug called Stalinon. The illness was characterized by greatly elevated intracranial pressure and by a spinal cord lesion in some cases (Alajouanine et al). Trimethyltin intoxication is much rarer; seizures are the main manifestation. Experimental studies in rats have shown neuronal loss in the hippocampus, largely sparing the Sommer sector, with later involvement of neurons in the pyriform cortex and amygdala (see review by LeQuesne).

A stereotyped episodic encephalopathy has been associated with bismuth intoxication, usually arising from the ingestion of bismuth subgallate. Large outbreaks have been reported in Australia and France (Burns et al, Buge et al). The onset of the neurologic disturbance is usually subacute, with a mild and fluctuating confusion, somnolence, difficulty in concentration, tremulousness, and sometimes hallucinations and delusions. With continued ingestion of bismuth, there occurs a rapid (24- to 48-h) worsening of the confusion and tremulousness, along with diffuse myoclonic jerks, seizures, ataxia, and inability to stand or walk. These symptoms regress over a few days to weeks when the bismuth is withdrawn, but some patients have died of acute intoxication. High concentrations of bismuth were found in the cerebral and cerebellar cortices and in the nuclear masses throughout the brain. These concentrations can be recognized as hyperdensities in the CT scan (Buge et al).
Industrial Toxins

Some of these, the heavy metals, have already been considered. In addition, a large number of synthetic organic compounds are widely used in industry and are frequent sources of toxicity, and the list is constantly being expanded. The reader is referred to the references at the end of the chapter, particularly to the most current text, edited by Spencer and Schaumburg, for details concerning these compounds. Here we can do little more than enumerate the most important ones: chlorinated diphenyls (e.g., DDT) or chlorinated polycyclic compounds (Kepone), used as insecticides; diethylene oxide (Dioxane); carbon disulfide; the halogenated hydrocarbons (methyl chloride, tetrachloroethane, carbon tetrachloride, trichloroethylene, and methyl bromide); naphthalene (used in moth repellants); benzene (gasoline); benzene and its derivatives [toluene, xylene, nitrobenzene, phenol, and amyl acetate (banana oil)] and the hexacarbon solvents (n-hexane and methyl n-butyl ketone).

With a few exceptions, the acute toxic effects of these substances are much the same from one compound to another. In general, the primary effect is on nonneurologic structures. Neural symptoms consist of varying combinations of headache, restlessness, drowsiness, confusion, delirium, coma, and convulsions, which, as a rule, occur late in the illness or preterminally. Some of these industrial toxins [carbon disulfide, carbon tetrachloride and tetrachloroethane, acrylamide, n-hexane, and diethylene glycol (Sterno; see Rollins)] may cause polyneuropathy, which becomes evident with recovery from acute toxicity. Extrapyramidal symptoms may result from chronic exposure to carbon disulfide. A syndrome of persistent fatigue, lack of stamina, inability to concentrate, poor memory, and irritability has also been attributed to chronic exposure to solvents, but these symptoms are quite nonspecific, and evidence for such a syndrome is unsupported by convincing experimental or epidemiologic studies.

Of the aforementioned industrial toxins, the ones most likely to cause neurologic disease are toluene (methyl benzene) and the hexacarbons. The chronic inhalation of fumes containing toluene (usually in glue, contact cement, or certain brands of spray paint) may lead to severe and irreversible tremor and cerebellar ataxia, affecting movements of the eyes (opsoclonus, ocular dysmetria) and limbs, as well as stance and gait. Cognitive impairment is usually associated; corticospinal tract signs, progressive optic neuropathy, sensorineural hearing loss, and hyposmia occur in some patients. Generalized cerebral atrophy and particularly cerebellar atrophy are evident in CT scans (Fornazzari et al, Hormes et al). Also, it has become apparent that acute toluene intoxication is an important cause of seizures, hallucinations, and coma in children (King et al).

The prolonged exposure to high concentrations of n-hexane or methyl-n-butyl ketone may cause a sensorimotor neuropathy, so-called glue-sniffer’s neuropathy (page 1132). These solvents are metabolized to 2,5-hexanediol, which is the agent that damages the peripheral nerves. The neuropathy may result from exposure in certain industrial settings (mainly the manufacture of vinyl products) or, more often, from the deliberate inhalation of vapors from solvents, lacquers, glue, or glue thinners containing n-hexane (see also Chap. 46). Impure trichloroethylene, through its breakdown product dichloroacetylene, has a predilection for the trigeminal nerve, which can be damaged selectively.

Hydrogen peroxide poisoning, usually by accidental ingestion, causes multiple small cerebral infarcts through a mechanism of gas embolus (Ijichi et al). Most cases have been reversible. According to Humberson et al (cited by Ijichi and colleagues) 120 mL of 35% hydrogen peroxide releases 14 L of oxygen on contact with organic tissue. The lung is involved, and the unmistakable brain lesions consist of tiny gas bubbles concentrated in parasagittal watershed areas.

ANTINEOPLASTIC AND IMMUNOSUPPRESSIVE AGENTS

The increasing use of potent antineoplastic agents has given rise to a diverse group of neurologic complications, the most important of which are subsequently summarized. A more detailed account of these agents—as well as the neurologic complications of corticosteroid therapy, immunosuppression, and radiation—can be found in the monograph edited by Rottenberg and in the review of Tuxen and Hansen. The neurotoxic effects of certain agents used in the treatment of brain tumors are also considered in Chap. 31.

Vincristine

This drug is used in the treatment of acute lymphoblastic leukemia, lymphomas, and some solid tumors. Its most important toxic side effect, and the one that limits its use as a chemotherapeutic agent, is a peripheral neuropathy. Paresthesias of the feet, hands, or both may occur within a few weeks of the beginning of treatment; with continued use of the drug, a progressive symmetrical neuropathy evolves (mainly sensory with reflex loss). Cranial nerves are affected less frequently but ptosis and lateral rectus, facial, and vocal cord palsies have been observed. Autonomic nervous system function may also be affected: constipation and impotence are frequent complications; orthostatic hypotension, atony of the bladder, and adynamic ileus are less frequent. The polyneuropathy due to vincristine is described more fully on page 1133. Inappropriate antidiuretic hormone secretion and seizures have been reported but are uncommon.

Although rarely noted in the literature, the authors have seen an instance of reversible posterior leukoencephalopathy with cortical blindness and headache after a single dose of vincristine, identical to the syndrome reported with the use of cyclosporine and FK-506 (Fig. 43-1). This radiologic appearance is also well known in hypertensive encephalopathy as discussed in Chap. 34. The main drugs implicated in this disorder are listed in Table 43-1. It has not been satisfactorily established if all such cases are the result of acute hypertension caused by the implicated drug or if there might be an additional direct toxic effect on the white matter.

The neural complications of vinblastine are similar to those of vincristine but are usually avoided because bone marrow suppression limits the dose of the drug that can safely be employed. Vinorelbine is a more recently introduced semisynthetic vinca alkaloid. It has much the same antitumor activity as vincristine but is supposedly less toxic.

Cisplatin

Cisplatin, a heavy metal that inhibits DNA synthesis, is effective in the treatment of gonadal and head and neck tumors, as well as carcinoma of the bladder, prostate, and breast. The dose-limiting factors in its use are nephrotoxicity and vomiting and a peripheral neuropathy (see page 1133). The latter manifests itself by numbness and tingling in fingers and toes, sometimes painful—symp-
Figure 43-1. Toxic reversible posterior leukoencephalopathy. Axial FLAIR magnetic resonance imaging in a patient with cortical blindness and severe headache days after receiving vincristine. This syndrome and radiographic findings are more typical following the use of cyclosporine, FK-506, and other chemotherapies. Compare to the similar conditions of hypertensive encephalopathy and toxemia shown in Fig. 34-29, page 729.

600 mg/m²). Symptoms may begin 1 to 3 days following the first dose and affect the feet and hands simultaneously. Autonomic neuropathy (orthostatic hypotension) may occur as well. The neuropathy is axonal in type, with secondary demyelination, and is at least partially reversible after discontinuation of the drug.

Procarbazine

This drug, originally synthesized as an MAO inhibitor, is now an important oral agent in the treatment of Hodgkin disease and other lymphomas and has found some use in bronchogenic carcinoma and malignant gliomas. It has also proved to be especially effective in the treatment of oligodendroglialomas. Neural complications are infrequent and usually take the form of somnolence, confusion, agitation, and depression. Diffuse aching pain in proximal muscles of the limbs and mild symptoms and signs of polynuropathy occur in 10 to 15 percent of patients treated with relatively high doses. A reversible ataxia has also been described. Procarbazine, taken in conjunction with phenothiazines, barbiturates, narcotics, or alcohol, may produce serious degrees of oversedation. Other toxic reactions, such as orthostatic hypotension, are related to the MAO inhibitory action of procarbazine.

L-Asparaginase

This enzymatic inhibitor of protein synthesis is used in the treatment of acute lymphoblastic leukemia. Drowsiness, confusion, delirium, stupor, coma, and diffuse EEG slowing are the common neurologic effects and are dose-related and cumulative. They may occur within a day of onset of treatment and clear quickly when the drug is withdrawn, or they may be delayed in onset, in which case they persist for several weeks. These abnormalities are at least in part attributable to the systemic metabolic derangements induced by L-asparaginase, including liver dysfunction.

In recent years, increasing attention has been drawn to cerebrovascular complications of L-asparaginase therapy, including ischemic and hemorrhagic infarction and cerebral venous and dural sinus thrombosis. Fineberg and Swenson have analyzed the clinical...
features of 38 such cases. These cerebrovascular complications are attributable to transient deficiencies in plasma proteins that are important in coagulation and fibrinolysis.

### 5-Fluorouracil

This is a pyrimidine analogue, used mainly as a secondary treatment of cancer of the breast, ovary, and gastrointestinal tract. A small proportion of patients receiving this drug develop dizziness, cerebellar ataxia of the trunk and the extremities, dysarthria, and nystagmus—symptoms that are much the same as those produced by cytarabine (Ara-C; see below). These abnormalities must be distinguished from metastatic involvement of the cerebellum and paraneoplastic cerebellar degeneration. The drug effects are usually mild and subside within 1 to 6 weeks after discontinuation of therapy. The basis of this cerebellar syndrome is not known.

### Methotrexate

Administered in conventional oral or intravenous doses, methotrexate (MTX) is not usually neurotoxic. However, given intrathecally to treat meningeal leukemia or carcinomatosis, MTX commonly causes aseptic meningitis, with headache, nausea and vomiting, stiff neck, fever, and cells in the spinal fluid. Very rarely, probably as an idiosyncratic response to the drug, intrathecal administration results in an acute paraplegia that may be permanent. The pathology of this condition has not been studied.

The most serious and more common of the neurologic problems associated with systemic MTX chemotherapy is a leukencephalopathy or leukomyelopathy, especially when given in combination with cranial or neuraxis radiation therapy (page 564). This develops several months after repeated intrathecal or high systemic doses of MTX, and a few milder cases are known to have occurred without radiation treatments, i.e., with oral or intravenous MTX alone such as the case reported by Worthley and McNeil. We have seen one such instance in a woman receiving oral MTX for a systemic vasculitis; no alternative explanation for widespread white matter changes and mild dementia could be discerned. Nonetheless, this must be quite uncommon. The full-blown syndrome consists of the insidious evolution of dementia, pseudobulbar palsy, ataxia, focal cerebral cortical deficits, or paraplegia. Milder cases show only radiographic evidence of a change in signal intensity in the posterior cerebral white matter (“posterior leukoencephalopathy”) that is similar to the imaging findings that follow cyclosporine use (see further on) and hypertensive encephalopathy (see Fig. 43-1). In severe cases, the brain shows disseminated foci of coagulation necrosis of white matter, usually periventricular, which can be detected with CT and MRI.

Mineralizing microangiopathy (fibrosis and calcification of small vessels, mainly in the basal ganglia) is yet another complication of MTX therapy. It may occur with MTX treatment or with cranial irradiation but is particularly common when both forms of treatment are combined. The present authors have the impression that the severe necrotic lesions possess features comparable to (and therefore maybe the result of) the coagulative necrosis of radiation encephalopathy.

### The Nitrosoureas

Carmustine (BCNU) and lomustine (CCNU) are nitrosoureas used to treat malignant cerebral gliomas. They are not neurotoxic when given in conventional intravenous doses, but intracarotid injection of the drugs may cause orbital, eye, and neck pain, focal seizures, confusion, and possibly focal neurologic deficits. Postmortem examinations of patients who had been treated with intravascular BCNU have disclosed a diffuse vasculopathy characterized by fibrinoid necrosis and microthrombi and diffuse foci of swollen axis cylinders and myelin vacuolization (Burger et al, Kleinschmidt-de Masters).

### Cytarabine (Ara-C)

This drug, long used in the treatment of acute nonlymphocytic leukemia, is not neurotoxic when given in the usual systemic daily doses of 100 to 200 mg/m². The administration of very high doses (up to 30 times the usual dose) has been shown to induce remissions in patients refractory to conventional treatments. It also may produce, however, a severe degree of cerebellar degeneration in a considerable proportion of cases (4 of 24 reported by Winkelman and Hines). Ataxia of gait and limbs, dysarthria, and nystagmus develop as early as 5 to 7 days after the beginning of high-dose treatment and worsen rapidly. Postmortem examination has disclosed a diffuse degeneration of Purkinje cells, most marked in the depths of the folia, as well as a patchy degeneration of other elements of the cerebellar cortex. Other patients receiving high-dose Ara-C have developed a mild, reversible cerebellar syndrome with the same clinical features. Patients more than 50 years of age are said to be far more likely to develop cerebellar degeneration than those younger than 50; therefore the former should be treated with a lower dosage (Herzig et al).

### Cyclosporine and Tacrolimus (FK-506)

These immunosuppressive drugs are used to prevent transplant rejection and to treat aplastic anemia and certain intrinsic immune diseases. Tremor is perhaps the most frequent side effect, particularly of tacrolimus, and myoclonus may be added. Sometimes these impart a stuttering character to speech. Headache and insomnia are common. Seizures may be a manifestation of toxicity, but the cause may lie with the other complications of organ transplantation and immunosuppression. The neurologic effects of these drugs have been reviewed by Wijdicks. As already noted, a posterior leukoencephalopathy syndrome resembling hypertensive encephalopathy—headache, vomiting, confusion, seizures, and visual loss (cortical blindness)—may follow the use of either drug (see Table 43-1). The appearance on CT scans and MRI of symmetrical signal and density changes mainly in the posterior white matter likewise conform to the pattern that is seen in hypertensive encephalopathy. Lesions may also appear subcortically in the frontal and parietal lobes. Interferon treatment for malignant melanoma and a number of other chemotherapeutic agents have been associated with the same condition. Hinchey and colleagues have described several such cases and suggested that cyclosporin alters the blood-brain barrier and that the fluid overload and hypertension which accompanies the use of cyclosporin underlies the radiologic changes. A variety of psychotic syndromes with delusions, paranoia, and visual hallucinations have also been ascribed to the use of these drugs (see Wijdicks).

### Thalidomide

Despite the catastrophic effects of thalidomide on the developing fetus (following its introduction as a soporific in 1957), this drug
has now found several specific uses in the treatment of immuno-
logic, neoplastic, and infectious diseases. It is effective in the treat-
ment of leprosy, erythema nodosum, and the oral ulcerations of
AIDS and Behcet disease. Experimental uses include suppression
of graft-versus-host reactions and inhibition of blood vessel prolif-
eration in vascular tumors such as renal cell cancer. A dose-depen-
dent sensory neuropathy is the limiting factor in its use, and serial
electrophysiologic testing is recommended if the medication is to
be prescribed for protracted periods. Of course, it must not be given
to a woman who is or might be pregnant.

Antibiotics and Other Medications
Numerous antibiotics, cardioactive medications, and other drugs
may have adverse effects on the central or peripheral nervous sys-
tem. Some of the latter are addressed on page 1134. Here we men-
tion mainly that penicillin and its derivatives such as imipenem,
and to a lesser degree, cephalosporins are capable of causing sei-
zures when high serum concentrations are attained. This is favored
in most instances by concomitant renal failure.

Other important examples of antibiotic toxicity are optic neu-
ropathy due to ethambutol toxicity; ototoxicity and neuromuscular
blockade from aminoglycosides and fluoroquinolone antibiotics
(page 216); peripheral neuropathy, encephalopathy, and an Anta-
buse-like reaction to alcohol in patients taking metronidazole; a
metronidazole induced polynychopathy, INH neuropathy and optic
neuropathy, and possibly a peripheral neuropathy due to chloram-
phenicol. A curious and reversible cerebellar syndrome due to met-
ronidazole with MRI signal changes in the dentate nuclei has been
reported by Woodruff and colleagues and by others.

The most notorious toxic consequences with this group of
drugs were seen with clioquinol, which was sold as Entero-vioform
and was used in many parts of the world to prevent traveler’s di-
arrhea and as a treatment for chronic gastroenteritis. In 1971, clinical
observations began to appear in medical journals of a subacute
myelo-opticoneuropathy (SMON). During the 1960s, more than
10,000 cases of this disease were collected in Japan by Tsubaki et
al. Usually the illness began with ascending numbness and weak-
ness of the legs, paralysis of sphincters, and autonomic disorder.
Later, vision was affected. The onset was acute in about two-thirds
of the cases and subacute in the remainder. The occurrence of these
neurologic complications was found to be related to the prolonged
use of clioquinol. In Japan the drug was withdrawn from the mar-
ket, and the incidence of SMON immediately fell, supporting the
theory that it was caused by the drug. Recovery was usually in-
complete. Two patients seen by the authors several years after onset
of the disease had been left with optic atrophy and a spastic-ataxic
paraparesis.

Also mentioned here, because neurologists are often asked to
consult on these cases, is a curious effect of the anesthetic propofol.
Seizures and myoclonic-like movements have been seen in a small
number of individuals, presumably as an idiosyncratic effect. Some-
times these take the form of less organized twitching, opis-
thotonus, or involuntary movements. While some inhaled anes-
thetics such as enflurane can cause seizures in susceptible patients,
propofol does not share the activating effects of the volatile anes-
thetics. In our own experience, the seizures have occurred in the
first hour after emergence from anesthesia but as many cases are
reported during induction, emergence, or after the use of the drug
(see Walder).

PART 5

DISEASES OF SPINAL CORD, PERIPHERAL NERVE, AND MUSCLE
Diseases of the nervous system may be confined to the spinal cord, where they produce a number of distinctive syndromes. These syndromes relate to the special physiologic and anatomic features of the cord, such as its prominent function in sensorimotor conduction and relatively primitive reflex activity; its long, cylindrical shape; its small cross-sectional size; its tight envelopment by meninges; the peripheral location of myelinated fibers next to the pia; the special arrangement of its blood vessels; and its relationship to the vertebral column. Woolsey and Young estimate that there are about 30 diseases known to affect the spinal cord, of which half are seen with regularity. These processes express themselves by a number of readily recognized syndromes and, as will be evident, certain diseases preferentially evoke one syndrome and not others. The syndromic grouping of the spinal cord disorders, which is in keeping with the general plan of this book, facilitates clinical diagnosis and reduces the number of ancillary examinations needed for confirmation.

The main syndromes to be considered in this chapter are: (1) a complete or almost complete sensorimotor myelopathy that involves most or all of the ascending and descending tracts (transverse myelopathy); (2) a combined painful radicular and transverse cord syndrome; (3) the hemicord (Brown-Séquard) syndrome; (4) a ventral cord syndrome, sparing posterior column function; (5) a high cervical-foramen magnum syndrome; (6) a central cord or syringomyelic syndrome; (7) a syndrome of the conus medullaris; and (8) a syndrome of the cauda equina (see also pages 1081 and 1082). In addition, an important distinction is made between lesions within the cord (intramedullary) and those that compress the cord from without (extramedullary). Most of the processes to be considered here cause one or the other of these syndromes, and each of them will be considered in the course of exposition of the major categories of spinal cord disease.

The anatomic and physiologic considerations pertinent to an understanding of disorders of the cord and of the spine can be found in Chaps. 3, 9 (particularly Fig. 9-5), and 11, on motor paralysis, somatic sensation, and back pain, respectively.

THE SYNDROME OF ACUTE PARAPLEgia OR QUADRIPLEGIA DUE TO COMPLETE TRANSVERSE LESIONS OF THE SPINAL CORD (TRANSVERSE MYELOPATHY)

This syndrome is best considered in relation to trauma, its most frequent cause, but it occurs also as a result of infarction or hemorrhage and with rapidly advancing compressive, necrotizing, demyelinating, or inflammatory lesions (transverse myelitis). Each of these categories of acute spinal cord disease is discussed in the following pages. For convenience we have included in this group radiation myelopathy, which is transverse but evolves subacutely.

Trauma to the Spine and Spinal Cord

Throughout recorded medical history, advances in the understanding of spinal cord disease have coincided largely with periods of warfare. The first thoroughly documented study of the effects of sudden total cord transection was by Theodor Kocher in 1896, based on his observations of 15 patients. During World War I, Riddoch—and later Head and Riddoch—gave the classic descriptions of spinal transection in humans; Lhermitte and Guillain and Barre are credited with refining these observations. Little could be done for those patients, however; fully 80 percent died in the first few weeks (from infections), and survival was possible only if the spinal cord lesion was partial. World War II marked a turning point in the understanding and management of spinal injuries. The advent of antibiotics and the ability to control skin, bladder, and pulmonary infections permitted the survival of unprecedented numbers of soldiers with spinal cord injuries and provided the opportunity for long-term observation. In special centers, such as the Long Beach, Hines, and West Roxbury Veterans Administration Hospitals in the United States and the Stoke Mandeville National Spinal Injuries Centre in England, the care and rehabilitation of the paraplegic were brought to a very high level. Studies conducted in these centers have greatly enhanced our knowledge of the functional capacity of the chronically isolated spinal cord. Kuhn, Munro, Martin and Davis, Guttmann, Pollock, and their associates, listed in the references, have made particularly important contributions to this subject.

Mechanisms of Spine and Spinal Cord Injury Although trauma may involve the spinal cord alone, the vertebral column is almost invariably injured at the same time. Often there is an associated head injury as pointed out in Chap. 35.

A useful classification of spinal injuries is one that divides them into fracture-dislocations, pure fractures, and pure dislocations. The relative frequency of these types is about 3:1:1. Except for bullet, shrapnel, and stab wounds, a direct blow to the spine is a relatively uncommon cause of serious spinal cord injury. In civilian life, most spinal injuries are the result of force applied at a distance from the site of spinal fracture and dislocation. All three types of spinal injury previously mentioned are produced by a similar mechanism, usually a vertical compression of the spinal column to which anteroflexion is added; or, the mechanism may be one of vertical compression and retroflexion (commonly referred to as hyperextension). The most important variables in the mechanics of vertebral injury are the structure of the bones at the level of the injury and the intensity, direction, and point of impact of the force.

In keeping with the mechanism of force applied at a distance, many spinal injuries are due to blows to the head. If the cranium is struck by a hard object at high velocity, a skull fracture occurs, the force of the injury being absorbed mainly by the elastic quality of the skull. If the traumatizing force is relatively soft yet unyield-
ing or is applied more slowly, the spine, and particularly its most mobile (cervical) portion, will be the part injured. If the neck happens to be rigid and straight and the force is applied quickly to the head, the atlas and the odontoid process of the axis may break. If the force is applied less quickly, an element of flexion or extension is added.

In the case of severe forward flexion injury, the head is bent sharply forward when the force is applied. The adjacent cervical vertebrae are forced together at the level of maximum stress. The anteroinferior edge of the upper vertebral body is driven into the one below, sometimes splitting it in two. The posterior part of the fractured body is displaced backward and compresses the cord. Concomitantly, there is tearing of the interspinous and posterior longitudinal ligaments. Less severe degrees of anteroflexion injury produce only dislocation. Vulnerability to the effects of anteroflexion (and to some extent to retroflexion injuries) is increased by the presence of cervical spondylosis or ankylosing spondylitis or by a congenital stenosis of the spinal canal.

In hyperextension injuries, the mechanism is one of vertical compression with the head in an extended position. Stress is mainly on the posterior elements (the laminae and pedicles) of the mid-cervical vertebrae (C4 to C6), which may be fractured unilaterally or bilaterally — and on the anterior ligaments. This dual disruption in the spinal architecture allows for displacement of one vertebral body on the adjacent one. The dislocation results in the cord being caught between the laminae of the lower vertebra and the body of the one above.

It should be pointed out that a hyperextension injury to the spinal cord commonly occurs without apparent damage or misalignment of the vertebrae when viewed radiologically. In these instances the spinal cord damage, which can be nonetheless profound and permanent, is caused by a sudden inward bulge of the ligamentum flavum or a transient vertebral dislocation followed by spontaneous realignment. This type of spinal cord damage, without radiologic evidence of fracture or dislocation, is particularly common in children. That rupture of the supporting ligamentous elements has nonetheless occurred can be revealed by gentle flexion and extension of the neck under radiologic observation which demonstrates slight dislocation of the vertebra (spinal instability).

Computed tomography (CT), magnetic resonance imaging (MRI), and plain lateral spine films are all satisfactory means of demonstrating the vertebral injury, but the tearing and bulging of ligaments from vertebral dislocation is dependably demonstrated only by MRI (or by contrast myelography) and can otherwise only be inferred from the spinal displacement. As mentioned, radiologic studies during cautious flexion or extension of the neck are the only way one can demonstrate instability from ligamentous rupture alone, although MRI may reveal signal changes in the traumatized ligaments.

Another mechanism of cord and spinal root injury, involving extremes of extension and flexion of the neck, is so-called whiplash or recoil injury, most often the result of an automobile accident. When a vehicle is struck sharply from behind, the head of the occupant is flung back uncontrollably; or, if a fast-moving vehicle stops abruptly, there is sudden forward flexion of the neck, followed by retroflexion. Under these conditions the occipitovertebral and sternocleidomastoid muscles and other supporting structures of the neck and head are affected much more often than the spinal cord or roots. Nevertheless, in rare instances, quadriparesis, temporary or permanent, results from a violent whiplash injury. The exact mechanism of neural injury in these circumstances is not clear; perhaps there is a transient posterior dislocation of a vertebral body, a momentary buckling of the ligamentum flavum, or retropropulsion of the intervertebral disc into the spinal canal. The presence of a congenitally narrow cervical spinal canal or of spinal diseases such as cervical spondylosis, rheumatoid arthritis, or ankylizing spondylitis adds greatly to the hazard of damage to the cord or roots. Also, preexisting spondylotic symptoms may be aggravated and become the source of chronic pain. There are in addition examples of spinal cord compression that result from the prolonged hyperextension of the cervical spine during a protracted period of stupor. This accounts for some cases of quadriplegia in opiate or other drug addicts following a period of sustained unresponsiveness (Ell et al). Arterial hypotension may be an added factor in some instances.

A special type of spinal cord injury, occurring most often in wartime, is one in which a high-velocity missile penetrates the vertebral canal and damages the spinal cord directly. In some cases the missile strikes the vertebral column without entering the spinal canal but virtually shatters the contents of the dural tube or produces lesser degrees of impairment of spinal cord function. Rarely, the transmitted shock wave will cause a paralysis of spinal cord function that is completely reversible in a day or two (spinal cord concussion, described further on).

Acute traumatic paralysis may also be the indirect consequence of a vascular mechanism. Fibrocartilaginous emboli from an intervertebral disc that has ruptured into radicular arteries or veins of the spinal cord may cause infarction. Or, a traumatic dissecting aneurysm of the aorta may occlude the segmental arteries of the spinal cord, as in the cases reported by Weisman and Adams and by Kneisley.

An analysis of 2000 cases of spinal injury collected from the medical literature by Jefferson up to 1927 showed that most vertebral injuries occurred at the levels of the first and second cervical, fourth to sixth cervical, and eleventh thoracic to second lumbar vertebrae. These preferred sites of injury are the same today. Industrial accidents most often involved the thoracolumbar vertebrae. Impact to the head with the neck flexed or sharply retroflexed, as mentioned earlier, was the main cause of injuries to the cervical region. These are not only the most mobile portions of the vertebral column but also the regions in which the cervical and lumbar enlargements of the cord greatly reduce the space between neural and bony structures. The thoracic cord is relatively small and its spinal canal is capacious; additional protection is provided by the high articular facets (making dislocation difficult) and limitations in anterior movement imposed by the thoracic cage.

In the authors’ general experience, the usual circumstances of spinal cord injury have been motor vehicle accidents, falls (mainly during a state of alcoholic intoxication), gunshot or stab wounds, diving accidents, motorcycle accidents, crushing industrial injuries, and birth injury in that order of frequency. The majority of the fatal cases have been associated with fracture-dislocations or dislocations of the upper cervical spine (C1 to C4 vertebrae) with resultant sudden respiratory paralysis. Among non-fatal cases, fracture-dislocation of the mid and lower cervical spine is the most frequent established mechanism of spinal cord injury in civilian life.

In the United States, the annual incidence of spinal cord injury is 5 cases per 100,000 population; males predominate (4:1). Each year about 3500 persons die in close relation to their injury, and another 5000 are left with complete or nearly complete loss of spinal cord function.
Pathology of Spinal Cord Injury

As a result of squeezing or shearing of the spinal cord, there is destruction of gray and white matter and a variable amount of hemorrhage, chiefly in the more vascular central parts. These changes, designated as traumatic necrosis of the spinal cord, are maximal at the level of injury and one or two segments above and below it. Rarely is the cord cut in two, and seldom is the pia-arachnoid lacerated. Separation of the constituent pathologic entities—such as hematomyelia, concussion, contusion, and hematorrhachis (bleeding into the spinal canal)—is of little value either clinically or pathologically. As a lesion heals, it leaves a gliotic focus or cavitation with variable amounts of hemosiderin and iron pigment. Progressive cavitation (traumatic syringomyelia) may develop after an interval of months or years and as it extends above the main lesion, lead to a delayed central or incomplete transverse cord syndrome. In most traumatic lesions, the central part of the spinal cord, with its vascular gray matter, tends to suffer greater injury than the peripheral parts. In some instances, the lesion is virtually restricted to the anterior and posterior gray matter, giving rise to segmental weakness and sensory loss in the arms with few long tract signs. This is the central cervical cord syndrome, also called the Schneider syndrome (see further on). Fragments of this syndrome commonly occur as transient phenomena that reverse over several days.

As with most lesions, the total clinical effect is composed of an irreversible structural component and a reversible disorder of function, each of which varies in degree. The extent and permanence of the clinical manifestations are, therefore, determined by the relative proportions of these two elements.

Experimental Spinal Cord Injury

Investigation of the pathophysiology of acute spinal cord injury dates from the experimental studies of Allen in the early 1900s. His method consisted of dropping graded weights onto the dura-covered thoracic cord of surgically prepared animals. The technique was refined over the years by precise measurements of the velocity, force, and direction of the dropped weights. This type of impact on the cord, of sufficient severity to render the animal immediately paraplegic and abolish sensory evoked responses from structures below the lesion, indicates that action potentials can no longer be conducted across the injured spinal cord segment. No histologic changes, by either light or electron microscopy, can be detected for several minutes after impact. The earliest tissue alterations consist of hyperemia and small hemorrhages in the central gray matter. By 1 h, the microscopic hemorrhages coalesce and become macroscopically visible. Tissue oxygen saturation is diminished in the region. Within 4 h, the central part of the cord swells and a spreading edema pervades the surrounding white matter; however, necrosis may not be evident for up to 8 h, an observation that has led to numerous strategies designed to spare the long tracts. Surgical intervention to minimize white matter edema—such as laminectomy and myelotomy—spinal cord cooling, hyperbaric exposure, and the administration of pharmacologic measures have been tried but have had no meaningful effects on the evolving lesion. The early administration of high-dose corticosteroids produces some benefit in experimental models, but the clinical benefits are questionable (see further on).

Certain mechanisms that are thought to be operative in the death of cerebral neurons exposed to ischemia or to traumatic forces have also been invoked in spinal cord injury. These include release of so-called excitotoxins such as glutamate and exposure of neurons to calcium and to agents that produce free radicals. The latter mechanism may explain the salutary effect of high doses of corticosteroids in experimental models rather than the ostensibly effect of these drugs on edema. Osterholm postulated that the initial event in acute impact injury was the release of norepinephrine from injured neurons in the central gray matter and that the subsequent vasoconstriction was responsible for both the central hemorrhagic and lateral white matter lesions. Later experimental work failed to substantiate this. Also, the contention that opioid release at the moment of trauma plays an important role in tissue damage has not been confirmed. The main problem with all the experimental work is that it only imperfectly reproduces the various types of spinal injury in humans.

Clinical Effects of Spinal Cord Injury

When the spinal cord is suddenly and virtually or completely severed, three disorders of function are at once evident: (1) all voluntary movement in parts of the body below the lesion is immediately and permanently lost; (2) all sensation from the lower (aboral) parts is abolished; and (3) reflex functions in all segments of the isolated spinal cord are suspended. The last effect, called spinal shock, involves tendon as well as autonomic reflexes. It is of variable duration (1 to 6 weeks as a rule but sometimes far longer) and is so dramatic that Riddoch used it as a basis for dividing the clinical effects of spinal cord transection into two stages, that of spinal shock and areflexia followed by the stage of heightened reflex activity. The separation of these two stages is not as sharp as this statement might imply but is nevertheless fundamental and useful for exposition. Less complete lesions of the spinal cord result in little or no spinal shock, and the same is true of any type of lesion that develops slowly. The features of complete spinal cord transection are presented later in detail for several reasons in addition to the practical value of understanding the evolution of cord lesions. They occupy a special place in classic neurology and are a guide to the processes that occur in nontraumatic and lesser types of cord damage.

Stage of Spinal Shock or Areflexia

The loss of motor function at the time of injury—tetraplegia with lesions of the fourth to fifth cervical segments or above, paraplegia with lesions of the thoracic cord—is accompanied by immediate atonic paralysis of bladder and bowel, gastric atony, loss of sensation below a level corresponding to the spinal cord lesion, muscular flaccidity, and almost complete suppression of all spinal segmental reflex activity below the lesion. As a result of their sudden separation from higher levels, the neural elements below the lesion fail to perform their normal function. However, the physiologic basis of this reflex segmental paralysis is incompletely understood as noted later. Also impaired in the segments below the lesion is the control of autonomic function. Vasomotor tone, sweating, and piloerection in the lower parts of the body are temporarily abolished. Systemic hypotension may be severe and contribute to the spinal cord damage. The lower extremities lose heat if left uncovered, and they swell if dependent. The skin becomes dry and pale, and ulcerations may develop over bony prominences. The sphincters of the bladder and the rectum remain contracted to some degree due to the loss of inhibitory influence of higher central nervous system (CNS) centers, but the detrusor of the bladder and smooth muscle of the rectum are atomic. Urine accumulates until the intravesicular pressure is sufficient to overcome the sphincters; then dribbles escape (overflow incontinence). There is also passive distention of the bowel, retention of feces, and absence of peristalsis (paralytic ileus). Genital reflexes (penile erection, bulbo cavernous reflex, contraction of darts muscle) are abolished or profoundly depressed.

The duration of the stage of spinal shock with complete are-
Stage of Heightened Reflex Activity

overly easy to elicit. Pressed until spasticity supervenes, at which time they become the motor neurons of the isolated segment of the cord, are superseded. Waves, electrophysiologic responses that reflect the functioning of and brainstem lesions that interrupt the corticospinal tracts. The F-humans, because spinal shock does not result from acute cerebral tract alone. This cannot be the significant factor, however, at least of spinal shock could result from interruption of the corticospinal tracts. Fulton found the facilitatory tracts in question to be the reticulospinal and vestibulospinal. Subsequent studies showed that in monkeys, some degree of spinal shock could result from interruption of the corticospinal tracts alone. The cat and monkey, is believed to be the sudden interruption of suprasegmental descending fiber systems that normally keep the spinal motor neurons in a continuous state of subliminal depolarization (ready to respond). In the cat and monkey, Fulton found the facilitatory tracts in question to be the reticulospinal and vestibulospinal. Subsequent studies showed that in monkeys, some degree of spinal shock could result from interruption of the corticospinal tracts alone. This cannot be the significant factor, however, at least in humans, because spinal shock does not result from acute cerebral and brainstem lesions that interrupt the corticospinal tracts. The F-waves, electrophysiologic responses that reflect the functioning of the motor neurons of the isolated segment of the cord, are suppressed until spasticity supervenes, at which time they become overly easy to elicit.

**Stage of Heightened Reflex Activity**

This is the more familiar neurologic state that emerges within several weeks or months after spinal injury. Usually, after a few weeks, the reflex responses to stimulation, which are initially minimal and sustained, become stronger and more easily elicitable and as time passes come to include additional and more proximal muscles. Gradually the typical pattern of heightened flexion reflexes emerges: dorsiflexion of the big toe (Babinski sign); fanning of the other toes; and later, flexion or slow withdrawal movements of the foot, leg, and thigh with contraction of the tensor fascia lata muscle (the last several features often referred to as “triple flexion”). Tactile stimulation of the foot may suffice as a stimulus, but a painful stimulus is more effective. The Achilles reflexes and then the patellar reflexes return. Retention of urine becomes less complete, and at irregular intervals urine is expelled by spontaneous contractions of the detrusor muscle. Reflex defecation also begins. After several months the withdrawal reflexes become greatly exaggerated, to the point of flexor spasms, and may be accompanied by profuse sweating, piloerection, and automatic emptying of the bladder (occasionally of the rectum). This is the “mass reflex,” which can be evoked by stimulation of the skin of the legs or by some interosseous stimulus, such as a full bladder. Varying degrees of heightened flexor reflex activity may last for years. Heat-induced sweating is defective, but reflex-evoked (“spinal”) sweating may be profuse (see Kniesley). Presumably, in such cases the lateral horn cells in much of the thoracic cord are still viable and are disinhibited. Above the level of the lesion, thermoregulatory sweating may be exaggerated and is accompanied by cutaneous flushing, pounding headache, hypertension, and reflex bradycardia. This syndrome (“autonomic dys-reflexia”) is episodic and occurs in response to a certain stimuli, such as a distended bladder or rectum. It has been ascribed to the reflex release of adrenalin from the adrenal medulla and of nor-epinephrine from the disinhibited sympathetic terminals caudal to the lesion.

Extensor reflexes eventually develop in most cases (18 of 22 of Kuhn’s patients who survived more than 2 years), but their appearance does not lead to the abolition of the flexor reflexes. The overactivity of extensor muscles may appear as early as 6 months after the injury, but this only happens, as a rule, after the flexor responses are fully developed. Extensor responses are at first manifest in certain muscles of the hip and thigh and later of the leg. In a few patients extensor reflexes are organized into support reactions sufficient to permit **spinal standing**. Kuhn observed that extensor movements were at first provoked most readily by a sudden shift from a sitting to a supine position and later by proprioceptive stimuli (squeezing of the thigh muscles) and tactile stimuli from wide areas. Marshall, in a study of 44 patients with chronic spastic paraplegia of spinal origin, found all possible combinations of flexor and extensor reflexes; the type of reflex obtained was determined by the intensity and duration of the stimulus (a mild prolonged noxious stimulus evoked an ipsilateral extensor reflex; an intense brief stimulus, a flexor response).

From these observations one would suspect that the ultimate posture of the legs—flexion or extension—does not depend solely on the completeness or incompleteness of the spinal cord lesion, as originally postulated by Riddoch. The development of **paraplegia in flexion** (extreme flexion of the hips and knees, as in a fetal position) relates also to the level of the lesion, being seen most often with cervical lesions and progressively less often with more caudal ones. Important also are repeated flexor spasms, which are more frequent with higher lesions, and the ensuing contractures ultimately produce a fixed flexor posture. Conversely, reduction of flexor spasms by elimination of noceptive stimuli (infected bladder, decubiti, etc.) favors an extensor posture of the legs (paraplegia in extension). According to Guttmann, the positioning of the limbs during the early stages of paraplegia greatly influences their ultimate posture. Thus, prolonged fixation of the paralyzed limbs in adduction and semiflexion favors subsequent paraplegia in flexion. Placing the patient prone or placing the limbs in abduction and extension facilitates the development of predominantly extensor postures. Nevertheless, strong and persistent extensor postures are usually observed only with partial lesions of the spinal cord.

Of some interest is the fact that many patients report sensory symptoms in segments of the body below the level of their transection. Thus, a tactile stimulus above the level of the lesion may be felt below the transection (synesthesia). Patients describe a variety of paresthesias, the most common being a dull, burning pain in the lower back and abdomen, buttocks, and perineum. We have encountered several patients in whom ach-ing testicular or rectal pain was a distressing problem. The pain may be intense and last for a year or longer, after which it gradually subsides. It persists after rhizotomy but can be abolished by anesthetizing the stump of the proximal (upper) segment of the spinal cord, according to Pollock and his collaborators. Transmission of sensation over splanch-nic afferents to levels of the spinal cord above the lesion, the conventional explanation, is therefore not the most plausible one.

The overactivity of neurons in the isolated segments of the spinal cord has several explanations. One assumes that suprasegmental inhibitory influences have been removed by the transection, so that afferent sensory impulses evoke exaggerated nociceptive
and phasic and tonic myotatic reflexes. But isolated neurons also become hypersensitive to neurotransmitters. Since the early experiments of Cannon and Rosenbluth it has been known that section of sympathetic motor fibers leaves the denervated structures hypersensitive to epinephrine; these authors also found the motor neurons in the isolated spinal segments to be abnormally sensitive to acetylcholine.

Various combinations of residual deficits (of lower and upper motor neurons and sensory neurons) are to be expected. Some of the resulting clinical pictures are complete or incomplete voluntary motor paralysis; a flaccid atrophic paralysis of upper limb muscles (if appropriate segments of gray matter are destroyed) with spastic weakness of the legs; a partial or rarely a complete Brown-Séquard syndrome (pages 51 and 140); and each of these occurs with variable sensory impairment in the legs and arms. High cervical lesions may result in extreme and prolonged tonic spasms of the legs due to release of tonic myotatic reflexes. Under these circumstances, attempted voluntary movement may excite intense contraction of all flexor and extensor muscles lasting for several minutes. Segmental damage in the low cervical or lumbar gray matter, destroying inhibitory Renshaw neurons, may release activity of remaining anterior horn cells, leading to segmental spasticity. Any residual symptoms persisting after 6 months are likely to be permanent, although in a small proportion of patients some return of function (particularly sensation) is possible after this time. Loss of motor and sensory function above the lesion, coming on years after the trauma, occurs occasionally and is due to an enlarging cavity in the proximal segment of the cord (see further on, under “Syringomyelia”).

Transitory Cord Injury (Spinal Cord Concussion) These terms refer to a transient loss of motor and/or sensory function of the spinal cord that recovers within minutes or hours but sometimes persists for a day or several days. In most instances the symptoms are already diminishing and few neurologic abnormalities are found at the time of the first examination. There are a number of such transient syndromes; bibrachial weakness; quadriplegia (occasionally hemiparesis); paresthesias and dysesthesias in a similar distribution to the weakness; or sensory symptoms alone (“burning hands syndrome”). In the first and last of these the central gray matter of the cervical cord is implicated. It is assumed that the cord undergoes some form of elastic deformation when the head is struck at the vertex or frontally and the cervical spine is compressed or hyperextended; however, the same effects can be produced by direct blows to the spine or forceful falls flat on the back and occasionally by a sharp fall on the tip of the coccyx. Little is known of the pathologic changes or the mechanisms that underlie these reversible syndromes.

Spinal cord concussion from direct impact is observed most frequently in athletes engaged in contact sports (football, rugby, and hockey). An incomplete and reversible myelopathy occurs referable to the level of the injury. A congenitally narrow cervical canal is thought to predispose to spinal cord concussion and to increase the risk of recurrence. As with cerebral concussion, particularly if there have been previous concussions, a difficult decision arises—whether to allow resumption of competitive sports. There are no reliable data on which to base this decision—only guidelines that favor continued participation if the deficit has been brief. Certainly, it is advisable in most cases to be certain that spinal instability has not been induced by the injury. This can be ascertained by obtaining flexion and extension radiographs of the affected spinal region. The subject is reviewed by Zwimpfer and Bernstein.

Central Cord Syndrome (Schneider Syndrome) and “Cruciate Paralysis” In the case of acute central cord damage (Schneider syndrome), the loss of motor function is characteristically more severe in the upper limbs than in the lower ones and particularly severe in the hands. Bladder dysfunction with urinary retention occurs in some cases, and sensory loss is often slight (hypopathia over the shoulders and arms may be the only sensory abnormality). Damage of the centrally situated gray matter may leave an atrophic, areflexic paralysis and a segmental loss of pain and thermal sensation from interruption of crossing pain and thermal fibers. Other cases are transient as noted earlier. Retroflexion injuries of the head and neck are the ones most often associated with the central cord syndrome, but hematomyelia, necrotizing myelitis, fibrocartilagenous embolism, and infarction due to dissection or compression of the vertebral artery in the medullary-cervical region are other causes (Morse).

According to Dickman and colleagues, approximately 4 percent of patients who survive injuries of the very rostral cervical cord demonstrate a related syndrome referred to by these authors as “cruciate paralysis.” The state is similar to the central cord syndrome except that the weakness is even more selective, being particularly limited to the arms, a feature that is attributable to the segregation of corticospinal fibers to the arms (rostral) and to the legs (caudal) within the pyramidal decussation. The arm weakness may be asymmetrical or even unilateral; sensory loss is inconsistent. The patients described have had injuries, basically contusions, of the C1–C2 region. Whether the lesion lies strictly within the decussating corticospinal tract or involves central gray matter is not always clear; MRI imaging has implicated the latter anatomic region (Inamasu et al). Sensory evoked potentials are normal, while magnetic stimulation of the corticospinal tract may be abnormal.

Examination and Management of the Spine-Injured Patient The level of the spinal cord and vertebral lesions can be determined from the clinical findings. Diaphragmatic paralysis occurs with lesions of the upper three cervical segments (an unrelated transient arrest of breathing is common in severe head injury). Complete paralyses of the arms and legs usually indicates a fracture or dislocation at the fourth to fifth cervical vertebrae. If the legs are paralyzed and the arms can still be abducted and flexed, the lesion is likely to be at the fifth to sixth cervical vertebrae. Paralysis of the legs and only the hands indicates a lesion at the sixth to seventh cervical level. Below the cervical region, the spinal cord segments and roots are not directly opposite their similarly numbered vertebrae (Fig. 44-1). The spinal cord ends at the first lumbar vertebra, usually at its rostral border. Vertebral lesions below this point give rise predominantly to cauda equina syndromes; these carry a better prognosis than injuries to the lower thoracic vertebrae, which involve both cord and multiple roots.

The level of sensory loss on the trunk, determined by perception of pinprick, is an accurate guide to the level of the lesion, with a few qualifications. (See Figs. 9-2 and 9-3 for maps of the sensory dermatomes.) Lesions of the lower cervical cord, even if complete, may show a sparing of sensation down to the nipple line because of the contribution of the C3 and C4 cutaneous branches of the cervical plexus, which variably innervate skin below the clavicle. Or, a lesion that involves only the outermost fibers of the spinothalamic pathways, sparing the innermost ones, results in a sensory
Figure 44-1. The relationship of spinal segments and roots to the vertebral bodies and spinous processes. The cervical roots (except C8) exit through foramina above their respective vertebral bodies, and the other roots issue below these bodies. (From Haymaker and Woodhall: Peripheral Nerve Injuries, 2nd ed. Philadelphia, Saunders, 1953, by permission.)

level (to pain and temperature) well below the level of the lesion. In all cases of spinal cord and cauda equina injury, the prognosis for recovery is more favorable if any movement or sensation is elicitable during the first 48 to 72 h.

If the spine can be examined safely, it should be inspected for angulations or irregularities and gently percussed to elicit signs of bony injury. Collateral injury of the thorax, abdomen, and long bones must always be sought.

In all cases of suspected spinal injury, the immediate concern is that movement (especially flexion) of the cervical spine be avoided. The patient should be placed supine on a firm, flat surface (with one person assigned, if possible, to keeping the head and neck immobile) and should be transported by a vehicle that can accept the litter. The board may be placed under the patient gently rolling him to one side with the head, neck, and body held in alignment. Preferably, the patient should be transported by an ambulance equipped with spine boards, to which the head is firmly fixed by straps. This provides a more effective means of immobilization than sandbags or similar objects placed on each side of the head and neck. On arrival at the hospital, it is useful to have the patient remain on the board until a lateral film or a CT or MRI of the cervical spine has been obtained.

A neurologic examination with detailed recording of motor, sensory, and sphincter function is necessary to follow the clinical progress of spinal cord injury. Common practice is to define the injury according to the standards of the American Spinal Injury Association and to assign the injury to a point on the Frankel Scale.

1. Complete: motor and sensory loss below the lesion
2. Incomplete: some sensory preservation below the zone of injury
3. Incomplete: motor and sensory sparing, but the patient is nonfunctional
4. Incomplete: motor and sensory sparing and the patient is functional (stands and walks)
5. Complete functional recovery: reflexes may be abnormal

Obviously, groups 2, 3, and 4 have a more favorable prognosis for recovery of ambulation than does group 1.

Once the degrees of injury to spine and cord have been assessed, some centers continue to administer methylprednisolone in high dosage (bolus of 30 mg/kg followed by 5.4 mg/kg every hour), beginning within 8 h of the injury and continued for 23 h. This measure, according to the multicenter National Acute Spinal Cord Study (Bracken et al) resulted in a slight but significant improvement in both motor and sensory function. Despite its widespread use, the therapeutic value of this measure has been questioned after careful reanalysis of the data (Nesathurai; Hurlbert) and it is no longer considered essential. Also, in a small series of patients, the administration of GM1 ganglioside (100 mg intravenously each day from the time of the accident) was found to enhance ultimate recovery to a modest degree (Geisler et al) but this finding has not been corroborated.

Next, radiologic examinations are undertaken to determine the alignment of vertebrae and pedicles, fracture of the pedicle or vertebral body, compression of the spinal cord or cauda equina due to malalignment, or bone debris in the spinal canal, and the presence of tissue damage within the cord. The MRI is ideally suited to display these processes but if it is not available myelography with CT scanning is an alternative. Instability of the spinal elements can often be inferred from dislocations or from certain fractures of the
pedicles, pars articularis, or transverse processes, but gentle flexion and extension of the injured areas must sometimes be undertaken and plain films obtained in each position.

If a cervical spinal cord injury is associated with vertebral dislocation, traction on the neck is necessary to secure proper alignment and maintain immobilization. This is best accomplished by use of a halo brace, which, of all the appliances used for this purpose provides the most rigid external fixation of the cervical spine. This type of fixation is usually continued for 4 to 6 weeks, after which a rigid collar may be substituted.

Concerning the early surgical management of spinal cord injury, there have been two schools of thought. One, represented by Guttman and others, advocates reduction and alignment of the dislocated vertebrae by traction and immobilization until skeletal fixation is obtained, and then rehabilitation. The other school, represented by Munro and later by Collins and Chehrazi, proposes early surgical decompression, correction of bony displacements, and removal of herniated disc tissue and intra- and extramedullary hematomas; often the spine is fixed at the same time by a bone graft or other form of stabilization. The issue of acute decompressive surgery remains contentious to the present day. The MRI scan has altered these empirical approaches by clearly demonstrating hematomas and other sources of compression that may be amenable to surgery. With complete spinal cord lesions, most surgeons do not favor surgery.

The results of the conservative and aggressive surgical plans of management have been difficult to compare and have not been evaluated with modern neurologic techniques. Collins, a participant in the National Institutes of Health (NIH) study of acute management of spinal cord injury 20 years ago, concluded that the survival rate was increased as a result of early surgical stabilization of fractures and fixation of the spine. Other neurosurgeons, however, have not been able to document a reduction in neurologic disability as a result of early operation, and they have increasingly inclined toward nonoperative management of both complete and partial spinal cord lesions (see, for example, Clark; Murphy et al). Most American neurosurgeons take the less aggressive stance, delaying operation or operating only on patients with compound wounds or those with progression or worsening of the neurologic deficit despite adequate reduction and stabilization. In any given case, the approach must be guided by the particular features of the patient’s injuries. A detailed description of the orthopedic and neurosurgical treatment of spinal fracture-dislocations is beyond the scope of a textbook of neurology but can be found in major textbooks of neurosurgery, and in the book on neurological intensive care by Ropper and colleagues listed in the References.

The greatest risk to the patient with spinal cord injury is in the first 10 days when gastric dilation, ileus, shock, and infection are threats to life. According to Messard and colleagues, the mortality rate falls rapidly after 3 months; beyond this time, 86 percent of paraplegics and 80 percent of quadriplegics will survive for 10 years or longer. In children, the survival rate is even higher according to DeVivo and colleagues, who found that the cumulative 7-year survival rate in spinal cord–injured children (who had survived at least 24 h after injury) was 87 percent. Advanced age at the time of injury and being rendered completely quadriplegic were the worst prognostic factors.

The aftercare of patients with paraplegia, in addition to psychologic support, is concerned with management of bladder and bowel disturbances, care of the skin, prevention of pulmonary embolism, and maintenance of nutrition. Decubitus ulcers can be prevented by frequent turning to avoid pressure necrosis, use of special mattresses, and meticulous skin care. Deep lesions require debridement and full-thickness grafting. At first, continual catheterization is necessary; then, after several weeks, the bladder can be managed by intermittent catheterization once or twice daily, using a scrupulous aseptic technique. Close watch is kept for bladder infection, which is treated promptly should it occur. Bacteruria is common and does not require treatment with antibiotics unless there is associated pyuria. Morning suppositories and periodically spaced enemas are the most effective means of controlling fecal incontinence. Chronic pain (present in 30 to 50 percent of cases) requires the use of nonsteroidal anti-inflammatory medication, injections of local anesthetics, and transcutaneous nerve stimulation. A combination of carbamazepine or gabapentin and either clonazepam or tricyclic antidepressants may be helpful in cases of burning leg and trunk pain. Recalcitrant pain may require more aggressive therapy, such as epidural injections of analgesics or corticosteroids or an implanted spinal cord stimulator that is applied to the dorsal columns, but often even these measures are ineffective. Spasticity and flexor spasms may be troublesome; oral baclofen, diazepam, or tizanidine may provide some relief. In permanent spinal paraplegia with severe stiffness and adductor and flexor spasms of the legs, intrathecal baclofen, delivered by an automated pump in doses of 12 to 400 mg/day, has also been helpful. The drug is believed to act at the synapses of spinal reflexes (Penn and Kroin). One must always be alert to the threat of pulmonary embolism from deep venous thrombi, although the incidence is surprisingly low after the first several months. Physical therapy, muscle re-education, and the proper use of braces are all important in the rehabilitation of the patient. All this is best carried out in special centers for rehabilitation of spinal cord injuries.

**Radiation Injury of the Spinal Cord**

Delayed necrosis of the spinal cord and brain is a well-recognized sequela of radiation therapy for tumors in the thorax and neck. A lower motor neuron syndrome, presumably due to injury to the gray matter of the spinal cord, may also follow radiation therapy that includes the cord in its ports, as described below. Mediastinal irradiation for Hodgkin disease or for other lymphomas is a typical setting for the development of these complications.

**Transient Radiation Myelopathy** An “early” type of radiation myelopathy (appearing 3 to 6 months after radiotherapy) is characterized mainly by sensations in the extremities. The paresthesias may be evoked or exacerbated by neck flexion (Lhermitte symptom). In one of our patients there was impairment of vibratory and position sense in the legs, but no weakness. The sensory abnormalities disappear after a few months and, according to Jones, are not followed by the delayed progressive radiation myelopathy described later. The pathology has not been fully elucidated, but there is said to be a spongy appearance of the white matter with demyelination and depletion of oligodendrocytes.

**Delayed Progressive Radiation Myelopathy** This is one of the most dreaded complications of radiation therapy. It is a progressive myelopathy that follows, after a characteristic latent period, the irradiation of malignant tissues in the vicinity of the spinal cord. The incidence of this complication is difficult to determine because many patients die of their malignant disease before the cord lesion fully evolves, but it is estimated to be between 2 and 3 percent
(Palmer). According to Douglas and colleagues, patients who have undergone hyperthermia as a treatment for cancer are particularly vulnerable to radiation myelopathy.

**Clinical Features** The neurologic disorder first appears 6 months or more after the course of radiation therapy, usually between 12 and 15 months (latent periods as long as 60 months or even longer have been reported). The onset is insidious, usually with sensory symptoms—paresthesias and dysesthesias of the feet or a Lhermitte phenomenon, and similar symptoms in the hands in cases of cervical cord damage. Weakness of one or both legs usually follows the sensory loss. Initially, local pain is notably absent, in distinction to the effects of spinal metastases. In some cases, the sensory abnormalities are transitory; more often, additional signs make their appearance and progress, at first rapidly and then more slowly and irregularly, over a period of several weeks or months, with involvement of the corticospinal and spinothalamic pathways. The neurologic disturbance may take the form of a Brown-Séquard syndrome, but with progression it is usually overtaken by a transverse myelopathy.

Reagan and coworkers, who have had much experience with this condition at the Mayo Clinic, describe yet another myelopathic radiation syndrome—namely, a slowly evolving amyotrophy, with weakness and atrophy of muscles and areflexia in parts of the body supplied by anterior horn cells of the irradiated spinal segments. Most patients with this form of the disease die within a year of onset. Knowledge of the pathology is incomplete. This syndrome is reminiscent of the delayed motor neuron myelopathy following electrical or lightning injury described in the next section.

The CSF in delayed progressive radiation myelopathy is normal except for a slight elevation of protein content in some cases. MRI demonstrates an abnormal signal intensity, decreased in T1-weighted and increased in T2-weighted images. Early in the course of the myelopathy the cord may be swollen, and there is often enhancement with gadolinium infusion. The cord lesion corresponds to the irradiated portal, which can be identified by the radiation effect on the marrow of the overlying vertebral bodies. The spinal cord lesion tends to be more extensive in rostral-caudal dimension than the usual vascular or demyelinating lesion. These are important points to establish, because a mistaken diagnosis of intraspinal tumor may lead to an unnecessary operation or further irradiation.

**Pathologic Findings** Corresponding with the level of the irradiated area and extending over several segments, there is an irregular zone of coagulation necrosis involving both white and gray matter, the former to a greater extent than the latter. Varying degrees of secondary degeneration are seen in the ascending and descending tracts. Vascular changes—necrosis of arterioles or hyaline thickening of their walls, with thrombotic occlusion of their lumens—are prominent in the most severely damaged portions of the cord. Most neuropathologists have attributed the parenchymal lesion to the blood vessel changes; others believe that the degree of vascular change is insufficient to explain the necrosis (Malamud et al; Burns et al). Certainly the most severe parenchymal changes in the cord are typical of infarction; but the insidious onset and slow, steady progression of the clinical disorder and the coagulative nature of the necrosis would then have to be explained by a steady succession of vascular occlusions. Exceptional instances, in which a transverse myelopathy has developed within a few hours (as described by Reagan et al), are more readily explained by thrombotic occlusion of a larger spinal artery.

Neurologists attached to tumor treatment centers are sometimes confronted with a patient who exhibits the late development (up to 10 to 15 years after radiation) of a slowly progressive sensory-motor paralysis of a limb (motor weakness predominates). The condition raises questions of recurrent tumor or the development of a local sarcoma, but the absence of a mass lesion and of pain, and the signs on neurologic examination are most consistent with a regional fibrosing plexopathy or neuropathy. Examples that we have seen are multiple cranial neuropathies after radiation of nasopharyngeal tumors, cervical and especially brachial neuropathies after laryngeal and breast cancers, and lumbosacral plexopathies and cauda equina damage with pelvic radiation. These are discussed further in Chap. 46 on diseases of the peripheral nerves.

**Treatment and Prevention** It must be kept in mind that radiation myelopathy is an iatrogenic disease and is therefore largely preventable. The tolerance of the adult human spinal cord to radiation—taking into account the volume of tissue irradiated, the duration of the irradiation, and the total dose—has been determined by Kagan and colleagues. These authors reviewed all of the cases in the literature up to 1980 and concluded that radiation injury could be avoided if the total dose was kept below 6000 cGy and was given over a period of 30 to 70 days, provided that each daily fraction did not exceed 200 cGy and the weekly dose was not in excess of 900 cGy. It is noteworthy that in the cases reported by Sanyal and associates, the amount of radiation surpassed these limits. Forewarned with this knowledge, radiation specialists have the impression that the incidence of this complication is decreasing.

A number of case reports remark on temporary improvement in neurologic function after the administration of corticosteroids. This therapy should be tried, because in some patients it appears to arrest the process short of complete destruction of all sensory and motor tracts. Claims have also been made of regression of early symptoms in response to the administration of heparin split products or hyperbaric oxygen, neither confirmed.

**Spinal Cord Injury due to Electric Currents and Lightning**

Among acute physical injuries to the spinal cord, those due to electric currents and lightning, despite their rarity, are of interest because of their unique clinical characteristics. Electrical forces can also injure the brain and peripheral nerves. These effects are noted briefly, since they are infrequent. It is the spinal cord that is most severely damaged.

**Electrical Injuries** In the United States, inadvertent contact with an electric current causes about 1000 deaths annually and many more nonfatal but serious injuries. About one-third of the fatal accidents result from contact with household currents.

The factor that governs the damage to the nervous system is the amount of current, or amperage, with which the victim has contact, not simply the voltage, as is generally believed. In any particular case, the duration of contact with the current and the resistance offered by the skin (this is greatly reduced if the skin is moist or a body part is immersed in water) are of critical importance. The physics of electrical injuries is much more complex than these brief remarks indicate (for a full discussion, see the reviews by Panse and by Winkelman).

Any part of the peripheral or central nervous system may be injured by electric currents and lightning. The effects may be immediate, which is understandable, but of greater interest are the instances of neurologic damage that occur after a delay of 1 day to
6 weeks (1 week on the average) and a rarer syndrome of anterior horn cell damage that arises many years later. The immediate effects are apparently the result of direct heating of the nervous tissue, but the pathogenesis of the delayed effects is not well understood. They have been attributed to vascular occlusive changes induced by the electric current, a mechanism proposed to underlie the delayed effects of radiation therapy (see earlier). However, the latent period is measured in many months or a few years rather than in days and the course is more often progressive than self-limited. Moreover, the few postmortem studies of myelopathy due to electrical injury have disclosed a widespread demyelination of long tracts, to the point of tissue necrosis in some segments, and relative sparing of the gray matter, but no abnormalities of the blood vessels. There may also be spinal fracture from the vigorous muscle contraction.

The syndrome of focal muscular atrophy occurring with a delay of weeks to years after an electric shock has been described by Panse under the title of *spinal atrophic paralysis*. It occurs when the path of the current, usually of low voltage, is from arm to arm (across the cervical cord) or arm to leg. Pain and paresthesias occur immediately in the involved limb but these symptoms are transient. Mild weakness, also unilateral, is immediate, followed in several weeks or months by muscle wasting, most often taking the form of segmental muscular atrophy. Occasionally the syndrome simulates that of amyotrophic lateral sclerosis or transverse myelopathy (most patients have some degree of weakness and spasticity of the legs). However, we have encountered two cases of asymmetric and profound atrophic weakness of the arms that began almost two decades after the shock and progressed over many years without long tract signs, both with a previously presumed diagnosis of amyotrophic lateral sclerosis. In contrast to injuries due to high-tension current, which affects mainly the spinal white matter (see earlier), it is the gray matter that is injured in cases of spinal atrophic paralysis, at least as judged from the clinical effects.

When the head is one of the contact points, the patient may become unconscious or suffer tinnitus, deafness, or headache for a short period following the injury. In a small number of surviving patients, after an asymptomatic interval of days to months, there has been an apoplectic onset of hemiplegia with or without aphasia or a straitial or brainstem syndrome, presumably due to thrombotic occlusion of cerebral vessels with infarction of tissue but this is not well studied.

**Lightning Injuries**  The factors involved in injuries from lightning are less well defined than those from electric currents, but the effects are much the same. The risk of being struck by lightning is about 30 times greater in rural areas than in cities. Direct strikes are often fatal; nearby strikes produce the neurologic damage described below. Topographic prominences such as trees, hills, and towers are struck preferentially, so these should be avoided; a person caught in the open should curl up on the ground, lying on one side with legs close together.

Arborescent red lines or burns on the skin indicate the point of contact of lightning. The path through the body can be approximately deduced from the clinical sequelae. Death is due to ventricular fibrillation or to the effects of intense desiccating heat on vital regions of the brain. Lightning that strikes the head is particularly dangerous, proving fatal in 30 percent of cases. Most persons struck by lightning are initially unconscious, irrespective of where they are struck. In those who survive, consciousness is usually regained rapidly and completely. Rarely, unconsciousness or an agitated-confusional state may persist for a week or two. There is usually a disturbance of sensorimotor function of a limb or all the limbs, which may be pale and cold or cyanotic. As a rule, these signs are also evanescent, but in some instances they persist, or an atrophic paralysis of a limb or part of a limb makes its appearance after a symptom-free interval of several months as in the case of electrical injury. Persistent seizures are surprisingly rare.

There are a few cases on record of recovery from a severe generalized polyneuropathy after lightning injury, but our only experience with one case suggested a severe and permanent generalized axonal damage (see Chap. 46).

### Myelopathy Following Spinal Anesthesia

This subject is introduced here with the other forms of cord injury for want of a better way to classify it. A transient and often asymmetric paraparesis is known to occur following prolonged spinal anesthesia but this is probably the temporary effect of the injected agents on cauda equina roots (Chap. 46). A more serious and permanent injury is caused by inadvertent injection of anesthetic directly into the conus medullaris (see Hamandi and colleagues and Wilkinson et al.). Leg weakness and numbness on one side are reported by the patient immediately with the injection (or upon awakening if sedation is used in addition). The MRI reveals an eccentrically placed traumatic lesion within the caudal spinal cord. This complication is rare but has occurred even when experienced anesthesiologists perform the procedure; misidentification of the L3-4 spinal interspace has been the usual problem. Flat tipped needles are as likely to cause injury as are ones with sharp beveled tips. Arachnoiditis from irritative agents may also cause a myelopathy (page 1078).

### Myelitis

In the nineteenth century, almost every disease of the spinal cord was labeled *myelitis*. Morton Prince, writing in *Dercum’s Textbook of Nervous Diseases* in 1895, referred to traumatic myelitis, compressive myelitis, and so on, obviously giving a rather imprecise meaning to the term. Gradually, however, as knowledge of neuropathology advanced, one disease after another was removed from this category until only the truly inflammatory ones remained.

Today the spinal cord is known to be the locus of a limited number of infective and noninfective inflammatory processes, some causing selective destruction of neurons, others affecting primarily white matter (tracts), and yet another group involving the meninges and white matter or leading to a necrosis of both gray and white matter. The currently accepted term for all these inflammatory conditions is *myelitis*. Other special terms are used to indicate more precisely the distribution of the process: if it is confined to gray matter, the proper expression is *poliomyelitis*; if to white matter, *leukomyelitis*. If approximately the whole cross-sectional area of the cord is involved, the process is said to be a *transverse myelitis* (although the term is still used more broadly for many myelitides); if the lesions are multiple and widespread over a long vertical extent, the modifying adjectives *diffuse* or *disseminated* are used. The term *meningomyelitis* refers to combined inflammation of meninges and spinal cord, and *meningoaradicularitis*, to combined meningeal and root involvement. An inflammatory process limited to the spinal dura is called *pachymeningitis*; and if infected material collects in the epidural or subdural space, it is called *epidural or subdural spinal abscess or granuloma*, as the case may be. The
adjectives acute, subacute, and chronic denote the tempo of evolution of myelitic symptoms—viz., more or less within days, 2 to 6 weeks, or more than 6 weeks, respectively. The main causes of myelitis are listed below.

**Classification of Inflammatory Diseases of the Spinal Cord**

I. Viral myelitis (Chap. 33)
   A. Enteroviruses (groups A and B Coxsackie virus, poliomyelitis, others)
   B. Herpes zoster
   C. Myelitis of AIDS
   D. Epstein-Barr virus (EBV), cytomegalovirus (CMV), herpes simplex
   E. Rabies
   F. Arboviruses–flaviviruses (Japanese, West Nile, etc.)
   G. HTLV-1 (tropical spastic paraparesis)

II. Myelitis secondary to bacterial, fungal, parasitic, and primary granulomatous diseases of the meninges and spinal cord (Chap. 32)
   A. *Mycoplasma pneumoniae*
   B. Lyme disease
   C. Pyogenic myelitis
      1. Acute epidural abscess and granuloma
      2. Abscess of spinal cord
   D. Tuberculous myelitis (Chap. 32)
      1. Pott disease with spinal cord compression
      2. Tuberculoma meningomyelitis
      3. Tuberculoma of spinal cord
   E. Parasitic and fungal infections producing epidural granuloma, localized meningitis, or meningomyelitis and abscess, especially certain forms of schistosomiasis (Chap. 32).
   F. Syphilitic myelitis (Chap. 32)
      1. Chronic meningoradiculitis (tabes dorsalis)
      2. Chronic meningomyelitis
      3. Meningovascular syphilis
      4. Gummatous meningitis including chronic spinal parapachymeningitis
   G. Sarcoid myelitis (Chap. 32)

III. Myelitis (myelopathy) of noninfectious inflammatory type (Chap. 36)
   A. Postinfectious and postvaccinal myelitis
   B. Acute and chronic relapsing or progressive multiple sclerosis (MS)
   C. Subacute necrotizing myelitis and Devic disease
   D. Myelopathy with lupus or other forms of connective tissue disease and antiphospholipid antibody
   E. Paraneoplastic myelopathy and poliomyelitis (Chap. 31)

From this outline it is evident that many different and totally unrelated diseases are under consideration and that a general description cannot possibly encompass such a diversity of pathologic processes. Overall, myelitis due to MS and postinfectious processes will be found to be the most common causes in practice. This was the case in the series collected by de Seze and colleagues. Excluding compressive myelopathy or trauma, 34 were found to have MS, 5 were postinfectious, and 5 had spinal infarctions; Nowak and coworkers reported a similar distribution. As noted in the previous outline, many of the myelitides are considered elsewhere in this volume in relation to the diseases of which they are a part. Here it is only necessary to comment on the principal categories and to describe a few of the common subtypes.

**Myelitis due to Viruses** (See also Chap. 33)

The enteroviruses, of which Coxsackie and poliomyelitis are examples, herpes zoster, arboviruses such as West Nile and the equine encephalitic viruses, and AIDS are the important members of this category. The enteroviruses in particular have an affinity for neurons of the anterior horns of the spinal cord and a motor nuclei of the brainstem (i.e., they are neuronotropic and cause a disease that can be generically termed poliomyelitis), and herpes zoster virus for the dorsal root ganglia; hence the disturbances of function are in terms of motor and sensory neurons, respectively, not of spinal tracts. West Nile virus is now showing the same proclivity for anterior horn cell damage. The onset of these conditions is acute and takes the form of a febrile meningomyelitis (see Chap. 33). Although there are systemic symptoms and sometimes cutaneous ones (in the case of zoster), it is the nervous system disorder that is most significant. The patient suffers the immediate effects of nerve cell destruction, and some degree of improvement nearly always follows as some neurons cells recover. Later in life, possibly as the neuronal loss of aging occurs in the anterior horns and dorsal root ganglia, there may be an apparent increased loss of strength in muscles originally weakened by poliomyelitis (“postpolio” syndrome, page 1104).

Relatively infrequent examples of transverse myelitis due to herpes simplex virus (HSV types 1 and 2), varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and SV70 virus (epidemic conjunctivitis) have been reported, some in patients with immunodeficiency states, mainly AIDS. The situation is more complex clinically, since most of these agents may also produce a postinfectious variety of myelitis, described further on in this chapter and in Chaps. 33 and 36. In HSV type 2 and CMV infections, there may also be an acute lumbosacral radiculitis with urinary retention; and in VZV infections, a sensory ganglionitis, vascularitis, or encephalitis. In a few cases of zoster myelitis, there may be evidence of an extensive inflammatory necrosis of the spinal cord with involvement of sensory and motor tracts. In other words, these conditions may at times simulate acute paraplegic and tetraplegic transverse syndromes of nonviral type. Herpes zoster is the best example. Pleocytosis in the cerebrospinal fluid and isolation of the viral DNA by the polymerase chain reaction or by direct culture from the cerebrospinal fluid (CSF) confirm the diagnosis of a primary viral infection as discussed in Chap. 33 (see Dawson and Potts).

There are other rare forms of poliomyelitic reactions of unknown, possibly viral etiology. One such condition presents as an acute febrile or afebrile meningoencephalitis and leaves all the limbs paralyzed and flaccid, sparing the brainstem and affecting the diaphragm to a variable extent. Several such patients have harbored a carcinoma or Hodgkin disease, and the pathology proved to be like that of a poliomyelitic viral infection rather than the usual paraneoplastic syndromes. Also, we would emphasize that we have cared for several patients who have had destruction of anterior horn cells due apparently to an enteroovirus other than poliomyelitis virus (see further on and Fig. 33-3, page 650).

Involvement of the white matter with sensory and motor paralysis below the level of a lesion has also been reported in so-called dumb rabies (in contrast to the usual form of “mad” or “fu-
The CSF contains small numbers of lymphocytes of T type (10 to 50 per cubic millimeter), normal concentrations of protein and glucose, and an increased content of IgG with antibodies to HTLV-I. The diagnosis is confirmed by the detection in the serum of the antibodies to the virus. Thinness of the spinal cord is evident on MRI, and subcortical cerebral white matter lesions may be seen as well. Neuropathologic study has documented an inflammatory myelitis with focal spongiform, demyelinating, and necrotic lesions, perivascular and meningeal infiltrates of inflammatory cells, and focal destruction of gray matter. The posterior columns and corticospinal tracts are the main sites of disease, most evident in the thoracic cord. It is strongly suspected but not established that the disease is due to the cytotoxic effect of the viral infection but autoimmune damage is an alternative possibility.

Because of slow evolution, the clinical picture can easily be confused with that of progressive spastic paraplegia of the hereditary variety, sporadic motor neuron disease, or the chronic phase of MS. There are also similarities with the AIDS myelopathy described earlier, but the other features of HIV infection are absent. Tropical spastic paraparesis and HTLV-I are also considered in the chapter on viral disease (page 647). There are anecdotal reports of improvement with intravenous administration of gamma globulin but these have not been consistent and had no effect in two of our patients.

**Myelitis Secondary to Bacterial, Fungal, Parasitic, and Granulomatous Diseases**

With few exceptions, this class of spinal cord disease seldom offers any difficulty in diagnosis. The CSF usually holds the clue to causation. In most cases, the inflammatory reaction in the meninges is only one manifestation of a generalized (systemic) disease process. The spinal lesion may involve primarily the pia-arachnoid (leptomeningitis), the dura (pachymeningitis), or the epidural space, e.g., taking the form of an abscess or granuloma; in the last circumstance, damage to the spinal cord is due to compression and ischemia. In some acute forms, both the spinal cord and meninges are simultaneously affected, or the cord lesions may predominate. Chronic spinal meningitis may involve the pial arteries or veins; and as the inflamed vessels become thrombosed, infarction (myelomalacia) of the spinal cord results. Chronic meningeal inflammation may provoke a progressive constrictive pial fibrosis (so-called spinal arachnoiditis) that virtually strangulates the spinal cord. In certain instances, spinal roots become progressively damaged, especially the lumbosacral ones, which have a long meningeal exposure. Posterior roots, which enter the subarachnoid space near arachnoidal villi (where CSF is resorbed), tend to suffer greater injury than anterior ones (as happens in tabes dorsalis). Interestingly, there are cases of chronic cerebrospinal meningitis that remain entirely without symptoms until the spinal cord or roots become involved.

The infrequent but unique bacterial myelitis caused by the atypical pneumonia agent *Mycoplasma pneumoniae* has come to be viewed as a postinfectious immune disease, as discussed on page 601. However, portions of the DNA from this organism have been found in the spinal fluid early in the course of illness in some cases (using the polymerase chain reaction), suggesting instead a direct bacterial infection of the spinal cord (see Chap. 32). It is not known whether antibiotic treatment alters the course of the illness.

*Syphilitic myelitis* is discussed on page 618. *Bacterial abscess of the spinal cord* (acute bacterial myelitis) is rare (especially in
comparison to epidural spinal abscess) and is only beginning to be recognized by MRI. At times it stands as a single pyogenic metastasis, but more often there has been spread from a contiguous infected surgical site or a fistulous connection with a superficial paraspinal abscess or a distant infection and subsequent bacteremia. As stated, spinal epidural abscess and granuloma are the more important representatives of this group.

Sarcoid myelitis (see also page 613) Sarcoid granulomas may present as one or more intramedullary spinal cord masses, as in the cases reported by Levivier and colleagues. In our experience the granulomatous lesion, which may be focal or multifocal, simulates demyelinating disease with respect to its tendency to relapse and remit and in its notable but inconsistent response to corticosteroids (page 614). An asymmetrical ascending paraparesis and bladder disturbance have been the main features in our patients. Usually there is evidence of disseminated sarcoidosis and the CSF is abnormal (increase in cells and protein), but we have encountered several instances of sarcoid restricted to the spinal cord before it was evident in the mediastinum (i.e., chest CT failing to demonstrate hilar adenopathy). Elevation of the spinal fluid IgG concentration and the presence of oligoclonal bands are typical but not constant in these cases of neurosarcoidosis; often there are activated histiocytes in the CSF. The use of angiotensin-converting enzyme levels in the CSF to distinguish sarcoidosis from MS suffers from the lack of normative values for this test, but it is said to be elevated in two-thirds of patients. The MRI is abnormal and the conus or other portions of the cord reveal intramedullary lesions. The most characteristic finding, however, is a multifocal-subpial nodular enhancement of the meninges adjacent to a lesion of the cord or nerve roots—a picture which to some extent resembles neoplastic meningeal infiltration. The diagnosis can be confirmed by mediastinal lymph node biopsy or by the less desirable method of biopsy of the spinal meninges and affected subpial cord.

A number of other rare granulomatous conditions have on occasion caused an intrinsic or, more often, an extrinsic compressive myelopathy, including brucellosis, xanthogranulomatosis, and eosinophilic granuloma. The diagnosis may be suspected if the systemic disease is apparent at the time, but in some instances only the histology of a surgical specimen reveals the underlying process.

Spinal Epidural Abscess This condition is worthy of emphasis because the diagnosis is often missed or mistaken for another disease, sometimes with disastrous results. Children or adults may be affected. Infection of the epidural space has a wide variety of sources. Staphylococcus aureus is the most frequent etiologic agent, followed in frequency by streptococci, gram-negative bacilli, and anaerobic organisms. An injury to the back, often trivial at the time, furunculosis or other skin or wound infection, or a bacteremia may permit seeding of the spinal epidural space or of a vertebral body. This gives rise to osteomyelitis with extension of the purulent process to the epidural space. Occasionally, it spreads from an infected disc. One frequent source is a septicemia in a drug addict following the use of nonsterile needles or the injection of contaminated drugs. In other cases organisms may be introduced into the epidural space during spinal surgery or rarely via a lumbar puncture needle during epidural or spinal anesthesia or from epidural injections of steroid or other therapeutic agents. The localization in these latter instances is over the lumbar and sacral roots. In these cases of cauda equina epidural abscess, back pain may be severe and neurologic symptomatology minimal unless the infection extends upward to the upper lumbar and thoracic segments of the spinal cord.

At first, the suppurative process is accompanied only by low-grade fever and aching local back pain, usually intense, followed within a day or several days by radicular pain in most cases. Headache and nuchal rigidity are sometimes present; more often there is just the persistent pain and a disinclination to move the back. After several more days, there is the onset of a rapidly progressive paraparesis and paraplegia or quadriplegia associated with sensory loss in the lower parts of the body and sphincteric paralysis. Percussion of the spine elicits considerable tenderness over the site of the infection. Examination discloses all the signs of a complete or partial transverse cord lesion, occasionally with elements of spinal shock if paralysis has evolved rapidly, which is rare. If a spinal puncture has been performed, the CSF contains a relatively small number of white cells (usually fewer than 100 per cubic millimeter), both polymorphonuclear leukocytes and lymphocytes, unless the needle penetrates the abscess, in which case pus is obtained. The protein content is high (100 to 400 mg/100 mL or more), but the glucose is normal. Elevation of the sedimentation rate and peripheral neutrophilic leukocytosis are important clues (often neglected) to the diagnosis (Baker et al).

Treatment The foregoing clinical findings call for immediate MRI (Fig. 44-2) or CT, the latter preferably with myelography, to demonstrate the abscess and determine its level. If not treated surgically by laminectomy and drainage at the earliest possible time, before the onset of paralysis, the spinal cord lesion, which is due in part to ischemia (compression mainly of veins), becomes more or less irreversible. Broad spectrum antibiotics in large doses must be given initially and the choice of treatment is then refined based on cultures from the abscess or the blood, or on the presumed source of bacteria. Cauda equina epidural abscess without neurologic signs may in many cases be treated solely with antibiotics, although some surgeons favor drainage, which must be undertaken in any case if osteomyelitis develops. When osteomyelitis of a vertebral body is the primary abnormality, the epidural extension may implicate only a few spinal sensory and motor roots, leaving long tracts and other intramedullary structures intact. In some cases with cervical epidural abscesses, stiff neck, fever, and deltoid-biceps weakness are the main neurologic abnormalities. Having emphasized the urgency of treatment, there are instances of small epidural abscesses that do not compress the cord and are limited to one or at most two levels for which we have avoided surgery by administering antibiotics alone. Antibiotics need to be continued for several weeks, and the patient should be examined at regular intervals and have sequential MRI scans of the affected region.

Even after apparently successful drainage and antibiotic treatment of an epidural abscess, there may be a slowly progressive and then stabilizing syndrome of incomplete cord compression. This is the result of formation of a fibrous and granulomatous reaction at the operative site. Distinguishing this inflammatory mass from residual epidural abscess may be difficult, even with enhanced MRI, but persistent fever, leukocytosis, and an elevated sedimentation rate should suggest that surgical drainage of the abscess was incomplete.

Spinal subdural bacterial infections also occur and, clinically, are virtually indistinguishable from epidural ones on clinical grounds. A clue is provided by the CT myelogram, in which the subdural lesion has a less sharp margin and a greater vertical extent. The difference in configuration is also appreciated on MRI. The epidural and subdural infections, if they smolder owing to delayed
Spinal Cord Abscess  This entity was first described by Hart in 1830 and, although it is rare, 73 cases had been reported by 1994 (Candon and Frerebeau). In some instances the patient was known to have had systemic bacterial infection, septicemia, or endocarditis; in others there was a contiguous abscess in the skin or subcutaneous tissues with a fistula to the spinal cord through an intervertebral foramen. Spinal cord abscess is a rare complication of spinal dysraphism or of a developmentally open fistulous tract. The symptoms are indistinguishable from those of epidural abscess—namely, spinal and radicular pain followed by sensory and motor paralysis; the CSF findings are also the same. Woltman and Adson described a patient in whom surgical drainage of an encapsulated intramedullary abscess led to recovery, and Morrison and associates reported a similar case caused by Listeria monocytogenes, which was successfully drained and the meningeal infection suppressed by ampicillin and chloramphenicol. MRI is the most useful diagnostic procedure.

Tuberculous Spinal Osteomyelitis (Pott disease)  Tuberculous osteitis of the spine with kyphosis (Pott disease) is well known in regions of endemic tuberculosis. Children and young adults are most often affected. The osteomyelitis is the result of reactivation of tuberculosis at a site previously established by hematogenous spread. An infectious endarteritis causes bone necrosis and collapse of a thoracic or upper lumbar (less often cervical) vertebral body resulting in a highly characteristic angulated kyphotic deformity (Fig. 44-3); any degree of additional rotary instability produces a gibbus deformity. Most patients have some evidence of active infection as evidenced by fever, night sweats, and other constitutional symptoms; the sedimentation rate is invariably elevated. A compressive myelopathy occurs in some cases as a result of the spinal deformity, but it is surprisingly infrequent and an epidural tuberculous abscess is a more common cause of cord compression (see below). What is surprising to us about Pott disease is the excellent result that may be obtained by external stabilization of the spine and long-term antituberculous medication. While there is some controversy regarding spinal surgery, it is required only in the presence of severe deformities or a compressive myelopathy.

Tuberculous Myelitis  Solitary tuberculoma of the spinal cord as part of a generalized infection is an extreme rarity. More often, pus or caseous granulation tissue may extrude from an infected vertebra and gives rise to an epidural compression of the cord (Pott paraplegia, as distinct from Pott disease). Occasionally a tuberculous menigitis may result in pial arteritis and spinal cord infarction. The paraplegia may appear before the tuberculous meningitis is diagnosed. All these forms of tuberculosis have become infrequent in the United States and western Europe but we see a new case every several years in patients who spent their earlier life in India or Africa. Additional comments can be found on page 611.

Meningomyelitis due to Fungus and Parasitic Diseases  A wide variety of fungal and parasitic agents may involve the spinal meninges. Such infections are rare, and some do not occur at all in the United States or are limited to certain geographic areas, particularly among immigrant populations. Actinomyces, Blastomyces, Coccidioides, and Aspergillus may invade the spinal epidural space via intervertebral foramina or by extension from a vertebral osteo-
myelitic focus. Cryptococcus, which causes meningoencephalitis and rarely a cerebral granuloma, in our experience seldom causes spinal lesions. Hematogenous metastases to the spinal cord or meninges may occur in both blastomycosis and coccidioidomycosis. Occasionally an echinococcal infection of the posterior mediastinum may extend to the spinal canal (epidural space) via intervertebral foramina and compress the spinal cord.

Schistosomiasis (bilharziasis) is a recognized cause of myelitis in the Far East, Africa, and South America. The spinal cord is a target for all three common forms of Schistosoma: S. haematobium, S. japonicum, and S. mansoni, but particularly the last of these (see page 627). The schistosomal ova evoke an intense granulomatous myelomeningoradiculitis. The lesions are destructive of gray and white matter, with ova in arteries and veins leading to vascular obstruction and ischemia (Scrimgeour and Gajdusek). Less often, a localized granuloma gives rise to a compressive cord syndrome and, rarely, the disease takes the form of an acute transverse myelitis with massive necrosis of cord tissue (Queiroz et al.). A pruritic “swimmer’s itch” at the site of entry of the parasite is reported by many patients in the days prior to the myelopathy. We have cared for two patients in whom the spinal cord in the low thoracic and lumbar region was infected approximately 3 weeks after they swam in contaminated water during an African vacation. The CSF showed only a slight elevation of protein, and there was no abnormality in the myelogram. Systemic and CSF eosinophilia is variable so cannot be depended on for diagnosis. The administration of praziquantel arrested the course of the illness, but the patients were left disabled.

**Myelitis of Noninfectious Inflammatory Type (Acute and Subacute Transverse Myelitis; See also Chap. 36 on Demyelinating Disease)**

The spinal cord disorders that make up this category take the form mainly of a leukomyelitis based on either demyelination or necrosis of the tracts in the spinal cord. The critical factor in their pathogenesis appears to be a disordered immune response, in some cases, to an infection, and in others, idiopathic. Varied clinical syndromes are produced, and the basic disease is classified in most textbooks under headings such as acute transverse myelitis, postinfectious myelitis, postvaccinal myelitis, acute MS, and necrotizing myelitis. While each of these conditions may affect other parts of the nervous system (most often the optic nerves or brain), often the only manifestations are spinal. The aforementioned myelopathies are sufficiently distinct to justify their separate classification, for in most cases they are isolated syndromes; but transitional cases sharing the clinical and pathologic attributes of more than one disease are encountered in any large clinical and pathologic material.

**Postinfectious and Postvaccinal Myelitides** The characteristic features of these diseases are (1) their temporal relationship to certain viral infections or vaccinations (see page 791); (2) the development of neurologic signs over the period of a few days; and (3) a monophasic temporal course, i.e., a single attack of several weeks’ duration with variable degrees of recovery and no recurrence. These diseases may involve the brain as well as the spinal cord, in which case the process is properly designated as acute disseminated encephalomyelitis (ADEM). On the basis of the clinical features of disseminated postinfectious encephalomyelitis and the animal model of experimental allergic encephalomyelitis (EAE), postinfectious myelitis is presumed to be immunologic in nature, reflecting an attack that is more or less confined to spinal cord myelin (see Chap. 36).

The usual history in these cases is for weakness and numbness of the feet and legs (less often of the hands and arms) to develop over a few days, at times longer, and for the sensory symptoms to ascend from the feet to the trunk. Paresthesias in the feet and legs are a common early symptom. Spinal cord disturbances and backache are also common in the first days. A slight asymmetry of the symptoms and signs, a sensory level on the trunk, or a Babinski sign clearly marks the disease as a myelopathy and serves to distinguish it from a rapidly progressive polyneuropathy such as the Guillain-Barré syndrome. Back pain of varying degree and headache and stiff neck may or may not be present. In about half of cases the patient can identify a recent infectious illness, usually a mundane upper respiratory syndrome, but there is no fever when...
the neurologic symptoms begin. The illness evolves over several days, sometimes a single day or on the other extreme, over one to 2 weeks. Despite the term transverse myelitis, fewer than half of cases demonstrate a “transverse” involvement of the cord; more often there is an incomplete corticospinal and spinothalamic syndrome affecting one side more than the other. As discussed later, after only a single episode, it is difficult to distinguish this myelitis from the first attack of MS.

Almost invariably the CSF contains lymphocytes and other mononuclear cells in the range of 10 to 100 per cubic millimeter (sometimes higher), with slightly raised protein and normal glucose content. There may be only 3 or 4 cells per cubic millimeter, or none, making the inflammatory aspect less clear. Oligoclonal bands are usually absent. In most instances that have come under our care, the MRI has shown some degree of T2 signal abnormalities and slight gadolinium enhancement extending over two or three spinal segments. The cord may be swollen in these regions (Fig. 44-4), however, several of our patients with mild and partial myelitis have had normal MRI studies.

Clinical variants of this syndrome are frequent in our experience; including: an almost pure paresthetic illness with posterior column dysfunction and the converse; a symmetrical paraparesis with analgesia below a level on the trunk but without involvement of deep sensation (a syndrome usually associated with infarction in the territory of the anterior spinal artery); a syndrome of variable sensory loss involving the leg and groin on one side or both; a purely lumbosacral or sacral myelopathy (conus syndrome with saddle analgesia and sphincter disturbances); and a partial Brown-Séquard syndrome.

In the past, postinfectious myelitis was most often observed in relation to the common exanthems (rubella, rubeola, varicella). The neurologic signs appeared as the rash was fading, often with a slight recrudescence of fever. Practically all human viruses have at one time or another been found to precede acute myelitis; the large DNA viruses such as Epstein-Barr and cytomegalovirus are most common, but hepatitis B, varicella, and entero- and rhinoviruses have been detected when sought systematically. Mycoplasma is almost unique as a bacterial trigger of the disease, but—as noted earlier—there is some uncertainty regarding its ability to cause direct infection rather than a postinfectious immune reaction; our interpretation of the existing information still favors a postinfectious etiology. In most instances the connection to a preceding infection is presumed but cannot be proved. Only the associations with EBV, CMV, and Mycoplasma seem fairly certain based on the regularity of their occurrence or perhaps the relative ease with which a recent infection can be documented by serologic tests. The list of antecedent infections is otherwise much the same as that for the Guillain-Barré syndrome with the notable absence of Campylobacter jejuni, which has not led to myelitis. It can be reasonably assumed that pharyngitis, respiratory infection, or conjunctivitis, etc., with or without fever, was a likely trigger for myelitis if it occurred during the several days before or even in a 2- to 3-week period prior to the neurologic symptoms. Severe headache with fever and subsequent myelitis suggests Mycoplasma, influenza or another atypical pneumonia agent, and the finding of abnormal liver function tests or severe pharyngitis with cervical adenopathy usually indicates EBV or, less often, CMV infection.

More difficult to understand are the large number of instances

Figure 44-4. MRI of acute postinfectious myelitis in the sagittal (A) and axial (B) planes. There is T2 signal change and other images showed mild enhancement after gadolinium infusion. The cord is slightly enlarged at the involved level.
of myelitis, including autopsy proven ones, in which the disease develops without an apparent antecedent infection. There is understandability in such cases as to whether the illness is the opening phase of MS of the type described below under “Demyelinative Myelitis.” In the numerous cases of transverse myelitis under our care, fewer than half have shown other signs of MS after 10 to 20 years (this is a far lower incidence than following a bout of optic neuritis). Also, there is an isolated form of relapsing myelitis, sometimes but not always triggered by an infection that does not manifest lesions elsewhere in the neuraxis and therefore has an ambiguous relationship to MS. Further discussion of acute transverse myelitis in relation to other demyelinating diseases can be found below and on pages 778 and 791.

The pathologic changes take the form of numerous subpial and perivenular zones of demyelination, with perivascular and meningeal infiltrations of lymphocytes and other mononuclear cells, and para-adventitial pleomorphic histiocytes and microglia (page 772). Taken in isolation, these changes cannot be clearly distinguished from those of MS.

Treatment Once symptoms begin, it is doubtful if any treatment is of consistent value. One’s first impulse, assuming the mechanism to be an autoimmune, is to administer high doses of corticosteroids—a practice we have followed but without conviction. Perhaps it is advisable to do so, but there is as yet no evidence that this alters the course of the illness. We have also used plasma exchange or intravenous immune globulin in several patients, with uncertain results, although this approach was seemingly helpful in a few patients who had an explosive clinical onset.

In general, the prognosis is better than the initial symptoms might suggest. Invariably, the myelitic disease improves, sometimes to a surprising degree, but there are examples in which the sequelae have been severe and permanent. Pain in the midthoracic region or an abrupt, severe onset usually indicates a poor prognosis (Ropper and Poskanzer). The authors have several times given a good prognosis for long-term recovery and assurance that no relapse will occur, only to witness a recrudescence of other symptoms at a later date, indicating that the original illness was MS.

Demyelinative Myelitis (Acute Multiple Sclerosis) The lesions of acute MS presenting as a myelitis share many of the features of the postinfectious type except that the clinical manifestations of the former tend to evolve more slowly, over a period of 1 to 3 weeks or even longer. Also, their relation to antecedent infections is less certain, and in most recorded examples such provocative events were lacking. Only the occurrence of subsequent attacks or additional lesions revealed by MRI or evoked potentials indicates that the basic illness is one of chronic recurrent demyelination, indistinguishable from the usual type of MS.

The most typical mode of clinical expression of demyelinative myelitis is with numbness that spreads over one or both sides of the body from the sacral segments to the feet, anterior thighs, and up over the trunk, with coincident but variable and usually asymmetric weakness and then paralysis of the legs. As this process becomes complete, the bladder is also affected. The sensorimotor disturbance may extend to involve the arms, and a sensory level can be demonstrated on the upper parts of the trunk. The CSF usually shows a mild lymphocytosis, as in the postinfectious variety, but it is as often normal. Oligoclonal bands may be absent with the first attack. Bakshi and colleagues have suggested that in myelitis due to MS, the changes seen on MRI occupy only a few adjacent spinal segments in comparison to the postinfectious lesions which have a longer vertical extent, but this has not been a consistent distinction in our experience. As a general rule, acute spinal MS is relatively painless and without fever, and the patient usually improves, with variable residual signs. Those cases with a necrotic element, Devic disease and the closely related subacute necrotic myelopathy, may stabilize but then worsen (see below).

The differential diagnosis of demyelinative myelitis is considered more fully in Chap. 36.

Treatment Corticosteroids, as outlined for the treatment of MS (page 787), may lead to a regression of symptoms, sometimes with relapse when the medication is discontinued (after 1 to 2 weeks). Other patients, however, show no apparent response, and a a proportion of cases have even continued to worsen while the medication was being given. Plasma exchange and intravenous immune globulin have reportedly been beneficial in individual cases, particularly in those with an explosive onset (see later). The results in our patients have been too variable to interpret.

Acute and Subacute Necrotizing Myelitis and Devic Disease (see page 781) In every large medical center, occasional examples of this disorder are found among the many patients who present with a subacute paraplegia or quadriplegia, sensory loss, and sphincter paralysis. The neurologic signs may erupt so precipitously that a vascular lesion is assumed. In most other cases, the disease evolves at a slower and usually stepwise pace, over several months or years (Katz and Ropper). It is the saltatory progression that we have found most characteristic of the disease and, when present, that distinguishes it best from other processes such as a tumor within the cord. Necrotizing myelopathy is distinguished from the more common types of transverse myelitis by a persistent and profound flaccidity of the legs (or arms if the lesion is cervical), areflexia, and atonicity of the bladder—all reflecting a widespread necrosis that involves both the gray and white matter of the spinal cord over a considerable vertical extent. This picture is unexpected for a spinal cord lesion and, therefore, is often mistakenly attributed to spinal shock or to a completely different process such as Guillain-Barré syndrome.

This combination of spinal cord necrosis and optic neuritis corresponds to the syndrome described by Devic in 1894 and named by him neuromyelitis optica (Devic disease, page 781). Nearly all neurologists agree that a similar clinical syndrome involving the optic nerve and spinal cord (usually without necrosis) may also be caused by postinfectious encephalomyelitis and probably more often, by MS. However, a case has been made for considering Devic disease as an entity apart from MS, as discussed in Chap. 36. It follows that subacute necrotic myelopathy without optic neuritis might also be the result of MS or even a postinfectious process; the relationship between all of these entities is ambiguous, as discussed in Chap. 36.

In both the isolated necrotic myelopathy and in Devic disease, a few or up to several hundred mononuclear cells per cubic millimeter and increased protein may be found in the CSF but oligoclonal banding is usually absent. Some cases show only an elevated protein concentration. More so than with postinfectious transverse myelitis, the MRI reveals extensive signal changes and gadolinium enhancement, usually extending over several spinal segments (Fig. 44-5). Highly characteristic on imaging studies performed weeks or more later is severe atrophy of the involved segments of cord. Persistent swelling of the affected region is more suggestive of spinal cord tumor or another type of inflammation, but the permissible duration of cord swelling in cases of necrotic myelopathy is
areas of residual inflammation and demyelination are often detected at the edges of the destructive lesions. For these reasons the current authors agree with Hughes in classifying this condition with the demyelinating diseases. Older lesions may have left the spinal cord cavitated or collapsed over a vertical extent of 5 to 20 cm, with conical extensions of necrosis into the gray matter above and below the area of transverse damage. In two cases of ours, in which death occurred many years after the onset of the myelitis, there were old cavitated and demyelinated, lesions in the cerebral white matter, typical of MS. Cases of this type emphasize the overlapping relationship between the necrotizing and demyelinating processes. Also, as alluded to earlier we have been unable to make a clear distinction between the necrotic myelopathy of Devic disease and the identical process occurring without optic neuropathy. The optic nerve lesions also tend to be of demyelinating type. In the cases of pure necrotic myelopathy described by Greenfield and Turner as well as by Hughes and in our own series (Katz and Ropper), patients of all ages and both sexes were affected.

Under the title “Subacute Necrotic Myelitis,” Foix and Alajouanine and later Greenfield and Turner described a disorder of adult men characterized by amyotrophic paraplegia that ran a progressive course over several months. An early spastic paraplegia evolved after a few weeks or longer into a flaccid, areflexic state. Sensory loss, at first dissociated and then complete, and loss of sphincteric control followed the initial paresis. The CSF protein was considerably elevated but there were no cells. In most ways, therefore, this process resembles subacute necrotizing myelopathy. Postmortem examinations in two of the cases of Foix and Alajouanine and in most subsequently reported ones have shown the lumbosacral segments to be the most severely involved. In the affected areas there was severe necrosis of both gray and white matter with appropriate macrophage and astrocytic reactions. However, the characterizing feature was thought to be an increase in the number of small vessels; their walls were thickened, cellular, and fibrotic (“angiodysplastic”), yet their lumens were not occluded. The veins were also thickened and surrounded by lymphocytes, mononuclear cells, and macrophages. These findings have been difficult to interpret. The possibility of spinal venous thrombosis in the pathogenesis has been emphasized, but in the case of Mair and Folkerts, only one thrombosed anterior spinal vein was seen; in the cases of Foix and Alajouanine, no thrombosed vessels were found. We believe the evidence of venous or other vascular occlusion to be unconvincing and are inclined to the view of Antoni and of others, who were impressed with the prominence of large arteries and veins and have reinterpretedit this pathologic process as an arteriovenous malformation (see further on). More importantly, in most cases of necrotic myelopathy that are not associated with a true vascular malformation, the vascular changes simply reflect a neovascular response to necrosis. Only when enlarged and abnormal vessels involve the surface and adjacent parenchyma of the cord does the disorder deserve to be designated as Foix-Alajouanine myelopathy; the remaining cases are of the inflammatory-necrotizing type described earlier, with a secondary neovascular response to necrosis.

Rarely, a similar syndrome is produced by an idiopathic granulomatous or necrotizing angiitis that is confined to the spinal cord (Caccamo et al). In these cases, there is a persistent and marked pleocytosis and some clinical stabilization with corticosteroids. One of our patients with a similar subacute necrotizing myelitis, responsive to corticosteroids, had mononuclear cells in the spinal fluid persistently over a year and died later as a result of inflam-

Figure 44-5. MRI of necrotic myelopathy in a patient without optic neuritis. Atrophy of the cord was evident several months later.
Sjögren Syndrome with Myelopathy

In addition to the well-described posterior root ganglionopathy and sensory neuritis, an inflammatory myelitis has been associated with Sjögren syndrome. In most instances, the patient has had overt symptoms of Sjögren syndrome, namely the sicca complex, and in others, the association has been established through serologic testing or by the finding of a characteristic inflammatory infiltration of minor salivary glands (from which a biopsy has been taken on the lip.) In many reported cases the myelopathy has simulated the myelitis of MS, even to the extent of including episodes of optic neuritis as in the cases described by Williams and colleagues and by de Seze and coworkers. This putative Sjögren myelitis has been in different cases acute, chronic, or relapsing and displayed MRI changes in the cord that would otherwise be considered to be postinfectious or demyelinating myelitis. The spinal fluid formula has varied but generally does not contain oligoclonal bands. Treatment with prednisone and cyclophosphamide or chlorambucil has been suggested.

The authors cannot comment authoritatively on this entity. There is little pathologic material on which to judge the association but the presence of other inflammatory lesions of the central and peripheral nervous system in Sjögren cases makes the existence of a myelitis plausible. Antibody tests (anti-SS-A and −SS-B) and possibly a biopsy of the minor salivary glands (at the junction of mucosa and epidermis of the lower lip) are justified in older women with unusual myelopathies or those with sicca symptoms; however, screening of all cases that otherwise suggest MS may not be practical. Whether our findings relative to the insensitivity of the serologic tests in patients with Sjögren disease and polyneuropathy also hold true for those with myelopathy is not known (see page 1141).

Paraneoplastic Myelitis

A subacute necrotic myelitis developing in conjunction with a bronchogenic carcinoma was first brought to notice by Mancall and Rosales in 1964. Several dozen cases have since been recorded, some in association with lymphomas, but the diseases must be rare. Actually, in cancer patients, intramedullary metastasis is more common as a cause of intrinsic myelopathy than is paraneoplastic disease and, of course, a compressive lesion is far more frequent. The clinical syndrome consists of a rapidly progressive painless loss of motor and then sensory tract function, usually with sphincter disorder. Imaging studies demonstrate an area of T2 signal change in the cord or may be normal. This is in distinction to the nodular enhancing appearance of an intramedullary metastasis or of extradural metastatic disease with cord compression. The larger problem of metastatic compression of the cord from the epidural space is discussed in a later part of the chapter.

The CSF may contain a few mononuclear cells and a slightly increased protein, or it may be normal. The lesions are essentially of necrotic type and respect neither gray nor white matter, but the latter is more affected. There is little or no evidence of an infective-inflammatory or ischemic lesion, for the blood vessels, apart from a modest cuffing with mononuclear cells, are normal. No tumor cells are visible in the CSF, meninges, or spinal cord tissue, and no virus has been isolated. Unlike the situation in most of the paraneoplastic neurologic disorders, there are no diagnostic markers by way of antineuronal antibodies. In particular, this myelopathy does not seem to be a component of the anti-Hu-associated encephalitis-neuropathy spectrum.

In some cases of paraneoplastic myelopathy, the degenerative changes are more chronic, confined to the posterior and lateral funiculi and they are often associated with a diffuse loss of cerebellar Purkinje cells. This latter syndrome has a disproportionately high association with ovarian carcinoma but has been observed with carcinoma of other types and with Hodgkin disease. All of the reported cases of these types have ended fatally. Steroids and plasmapheresis were of no clear value. A special but rare variety of anterior horn cell destruction resembling motor neuron diseases is known to occur rarely with certain lymphomas; it is discussed with the paraneoplastic syndromes in Chap. 31.

Subacute Spinal Neuritis

Whitely and colleagues have drawn attention to a rare but distinctive form of encephalomyelitis of unknown cause, characterized clinically by tonic rigidity and intermittent myoclonic jerking of the trunk and limb muscles and by painful spasms of these muscles evoked by sensory or emotional stimuli. In the late stages of the disease, signs of brainstem involvement may appear which are usually progressive over a period of several weeks, months, or a year or longer; consciousness is preserved. However, the cases we have observed remained confined to several contiguous spinal segments, usually the upper abdomen and lower thorax. The CSF may be normal or show a mild lymphocytosis and increase in protein content. This is probably the same disorder that had been described earlier by Campbell and Garland under the title of subacute myoclonic spinal neuritis and
later by Howell and coworkers, as noted on page 89. The disorder under discussion must be differentiated clinically from the syndrome of continuous muscle fiber activity of Isaacs and the "stiff man" syndrome (see page 1279) and focal tetanus. The last of these lacks the myoclonic nature and progressive course of spinal neuritis and, of course, typically follows clostridial infection.

The brunt of the pathologic process in fatal cases, falls on the cervical portion of the spinal cord. Widespread loss of intermuncial neurons with relative sparing of the anterior horn cells, neunonophagia of internuncial neurons, reactive gliosis and microglial proliferation, conspicuous lymphocytic cuffing of small blood vessels, and scanty meningeal inflammation are the main findings. Involvement of the white matter is less marked.

The pathophysiology of the rigidity in these cases is not well understood but is presumed to be due to the impaired function (or destruction) of Renshaw cells, with the release of tonic myotatic reflexes (Penry et al). The painful spasms and dysesthesias relate in some way to neuronal lesions in the posterior horns of the spinal cord and dorsal root ganglia. Whitely and Lhermitte and their coworkers have proposed that these cases probably represent a rare and obscure form of viral myelitis.

Myoclonic jerking of the trunk and limbs in a focal or segmental distribution is probably due to neuronal damage that is limited to the spinal cord. We have seen several such cases, usually with regional abdominal or thoracic myoclonus, in otherwise healthy patients and have been unable to determine its cause. The spinal fluid has been normal. Anticonvulsants and antispasticity drugs in some combination may partially suppress the myoclonus, and local injection of botulinum toxin has improved the symptoms in some. A similar syndrome in a few cases has complicated vertebral or spinal artery angiography (see later). A paraneoplastic variety, not of the stiff-man type, has been proposed, as in the case described by Roobol and colleagues, but its nature has not been fully elucidated.

**VASCULAR DISEASES OF THE SPINAL CORD**

In comparison with the brain, the spinal cord is an uncommon site of vascular disease. Blackwood, in a review of 3737 necropsies at the National Hospital for Nervous Diseases, London, in the period 1903 to 1958, found only 9 cases of spinal cord infarction, but in general hospitals such as ours, the incidence (on clinical grounds) is somewhat higher. The spinal arteries tend not to be susceptible to atherosclerosis, and emboli rarely lodge there. Of all the vascular disorders of the spinal cord, infarction, dural fistula, bleeding, and arteriovenous malformation are the only ones that are encountered with any regularity, but they are rare in comparison with demyelinating myelitis or compression by tumor. In current practice, most cases of infarction have developed in relation to operations on the aorta, usually the thoracic portion, where the aorta must be clamped for some period. An understanding of these disorders requires some knowledge of the blood supply of the spinal cord.

**Vascular Anatomy of the Spinal Cord**

The blood supply of the spinal cord is derived from a series of segmental vessels arising from the aorta and from branches of the subclavian and internal iliac arteries (Fig. 44-6). The most important branches of the subclavian are the vertebral arteries, small branches of which give rise to the rostral origin of the anterior spinal artery and to smaller posterolateral spinal arteries and constitute the major blood supply to the cervical cord. The thoracic and lumbar cord is nourished by segmental arteries arising from the aorta and internal iliac arteries. Segmental branches of the lateral sacral arteries supply the sacral cord.

A typical segmental artery divides into an anterior and a posterior ramus (Fig. 44-7). Each posterior ramus gives rise to a spinal artery, which enters the vertebral foramen, pierces the dura, and supplies the spinal ganglion and roots through its anterior and posterior radicular branches. Most anterior radicular arteries are small and some never reach the spinal cord, but a variable number (four to nine), arising at irregular intervals, are much larger and supply most of the blood to the spinal cord. Tributaries of the radicular arteries supply blood to the vertebral bodies and surrounding ligaments. The venous drainage of the marrow is into the posterior veins forming the spinal plexus. Their importance relates to the pathogenesis of fibrocartilaginous embolism (see further on).
Lazorthes, in his thorough review of the circulation of the spinal cord, divides the radiculomedullary arteries into three groups: (1) upper or cervicothoracic, which are derived from the anterior spinal arteries and branches of thyrocervical and costovertebral arteries; (2) intermediate or middle thoracic (T3 to T8 cord segments), usually from a single T7 radicular artery; and (3) lower or thoracolumbar, from a large T10 or L1 anterior radicular artery called the *arteria radicularis magna* or the *artery of Adamkiewicz*. This artery may supply the lower two-thirds of the cord, but in any individual the precise area supplied by this or any other anterior radiculomedullary artery varies greatly and one cannot predict what proportion of cord will be infarcted if one of these vessels is occluded. The junction between the vertebral spinal and aortic circulations typically lies at the T2–T3 spinal segment, but most ischemic lesions lie well below this level.

The anterior medullary arteries form the single anterior median spinal artery, which runs the full length of the cord in the anterior sulcus and gives off direct penetrating branches via the central (sulco-commissural) arteries. These penetrating branches supply most of the anterior gray columns and the ventral portions of the dorsal gray columns of neurons (see Fig. 44-7). The peripheral rim of white matter of the anterior two-thirds of the cord is supplied from a pial radial network, which also originates from the anterior median spinal artery. **Thus, the branches of the anterior median spinal artery supply roughly the ventral two-thirds of the spinal cord.** The posterior medullary arteries form the paired posterior spinal arteries that supply the dorsal third of the cord by means of direct penetrating vessels and a plexus of pial vessels (similar to that of the ventral cord, with which it anastomoses freely). Within the cord substance, then, there is a “watershed” area of capillaries where the penetrating branches of the anterior median spinal artery meet the penetrating branches of the posterior spinal arteries and the branches of the circumferential pial network. All spinal segments, because of the variable size of collateral arteries, do not have the same abundance of circulatory protection.

Normally there are 8 to 12 anterior medullary veins and a greater number of posterior medullary veins arranged fairly close to one another at every segmental level. They drain into radicular veins. In addition, a network of valveless veins extends along the vertebral column from the pelvic venous plexuses to the intracranial venous sinuses without passing through the lungs (Batson’s plexus) and is considered a route for metastatic disease from the pelvis.

**Infarction of the Spinal Cord (Myelomalacia)**

Ischemic softening of the spinal cord usually involves the territory of the anterior spinal artery, i.e., a variable vertical extent of the ventral two-thirds of the spinal cord. Infarctions in this territory are
relatively uncommon, representing 1.2 percent of all strokes (Sandson and Friedman). The resulting clinical abnormalities are generally referred to as the anterior spinal artery syndrome, described by Spiller in 1909. Atherosclerosis and thrombotic occlusion of the anterior spinal artery is quite uncommon, as noted, and infarction in the territory of this artery is more often secondary to disease of the extravertebral collateral artery or to disease of the aorta—either advanced atherosclerosis, a dissecting aneurysm, or intraoperative surgical occlusion of the aorta—which compromises the important segmental spinal arteries at their origins. An ischemic myelopathy has been reported in cocaine users, preceded sometimes by episodes of cord dysfunction resembling transient ischemic attacks. Cardiac and aortic surgery, which requires clamping of the aorta for more than 30 min, and aortic arteriography may occasionally be complicated by infarction in the territory of the anterior spinal artery; more often in these circumstances damage to central neuronal elements is greater than that to anterior and lateral funiculi, as described below. The special ischemic myelopathy caused by a spinal dural-based arteriovenous fistula is discussed further on.

Rarely, poliarteritis nodosa may cause occlusion of a spinal medullary artery. Systemic cholesterol embolism arising from a severely atheromatous aorta may have the same effect. This latter type of embolism is prone to occur after surgical procedures, angioplasty, or cardiopulmonary resuscitation. For unexplained reasons, the spinal cord infarction sometimes follows the procedure by up to 3 weeks, as noted in Dahlberg’s series. In almost all such patients, other evidence of widespread embolism can be expected. Infarction may result from systemic hypotension, the most vulnerable part being of the thoracic segments of the cord. One of our cases occurred during a bout of diabetic coma.

Among the most curious, albeit rare causes of cervical cord infarctions is dissection of the extracranial vertebral arteries, either unilateral or bilateral. Presumably ischemia in the territories of the anterior spinal arteries causes anterior and central cord ischemia. In two cases of this nature that have been brought to our attention there was an asymmetric brachial diplegia and a suspended sensory loss, preceded by radicular and neck pain. The patients reported by Weidauer and colleagues are representative and there are numerous other case reports. A few patients have vertigo at the onset, pointing to the vertebral artery involvement. We have also seen instances of myelomalacia in adolescents and young adults in whom no aortic or spinal arterial disease could be demonstrated. Possibly, some of these were due to embolization of disc (nucleus pulposus) material into the local vasculature (see further on).

A quite different progressive ischemic necrosis of the cord occurs in the neighborhood of an arteriovenous malformation or dural fistula and is considered later in this chapter (see also the subacute necrotic myelitis of Foix and Alajouanine, described earlier).

The clinical manifestations of spinal arterial occlusion will, of course, vary with the level and portions of the cord that are infarcted, but common to practically all cases of infarction in the territory of the anterior spinal artery is pain in the neck or back and the development of motor paralysis and loss of pain and thermal sensation below the level of the lesion, accompanied by paralysis of sphincteric function. Rarely, infarction is preceded by transient spinal ischemic attacks as has been emphasized in cases related to cocaine use. The symptoms may develop instantaneously or, more often in our experience, over an hour or two, in any case, more rapidly than in the inflammatory myelitides. Radicular pain corresponding to the upper level of the lesion is sometimes a complaint. Paralysis is usually bilateral, occasionally unilateral, and rarely complete. Also reported is a bibrachial paralysis as a fragment of the anterior spinal artery syndrome, as mentioned earlier. Except in high cervical lesions, the sensory changes are dissociated; i.e., pain and temperature sensations are lost (due to interruption of the spinothalamic tracts), but vibration and position sense are unimpaired (due to sparing of posterior columns). In this respect the syndrome differs from the myelopathy of trauma, as both mentioned earlier a similar syndrome occasionally results from myelitis. In cases that cause a complete transverse myelopathy, the limbs are initially flaccid and areflexic, as in spinal shock from traumatic lesions, followed after several weeks by the development of spasticity, and some degree of voluntary bladder control (unless sacral segments have been infarcted). Some patients regain a substantial degree motor function, mainly in the first month but extending over a year (Sandson and Friedman; Cheshire et al).

Infarction in the territory of the posterior spinal arteries is uncommon and the corresponding syndrome is not stereotyped. It may occur with surgery or trauma of the spine or rarely with vertebral artery dissections.

Most spinal cord infarctions can be detected by MRI. After a few days, there are obvious lesions on the T2 image sequences, presumably reflecting edema extending over several levels. There may be slight enhancement after infusion of gadolinium. It is notable, however, that the MRI taken in the first hours or days is often normal. The reason for this delay in the appearance of the imaging findings is not known. After several weeks there is myelomalacia, and in the chronic stages, the infarcted region collapses and is shown to be attenuated on MRI.

A dissecting aneurysm of the aorta—which is characterized by intense interscapular and/or chest pain (occasionally it is painless), widening of the aorta, and signs of impaired circulation to the legs or arms and various organs—gives rise to a number of myelopathic syndromes. This neurologic syndrome was first described by Kalischer in 1914 and the aortic lesion leading to dissection, according to Erdheim, was a medianecrosis. Noteworthy is the fact that this vascular pathologic change has not been observed in dissection of the carotid and vertebral arteries. The most common syndromes of aortic dissection, according to Weisman and Adams, are (1) paralysis of the sphincters and both legs with sensory loss usually below T6, (2) ischemic infarction of the cord confined to the gray matter, in which case there is an abrupt onset of muscle weakness or myoclonus and spasms in the legs but no pain or sensory loss, (3) obstruction of the origin of a common carotid artery with hemiplegia, and, less commonly, (4) obstruction of a brachial artery with a sensorimotor neuropathy of the limb.

With regard to aortic aneurysm surgery, paraplegia is extremely uncommon after procedures performed on the infrarenal segment but occurs as frequently as 5 to 10 percent following repair of thoracoabdominal aneurysms. Not easily explained is the observation that up to a quarter of these instances of myelopathy do not appear for several days (one case at 8 days in our experience) postoperatively. The article by Lintott and colleagues should be consulted for further details.

In the past, aortography was sometimes complicated by an acute myelopathy; the authors had observed a number of such cases, and Killen and Foster reviewed 43 examples of this accident. The most striking examples, fortunately rare, are now observed as complications of vertebral angiography, resulting in high cervical infarction, similar in most ways to the aforementioned spinal infarction from extracranial dissection of the vertebral artery. The
onset of sensorimotor paralysis is immediate, and the effects are often permanent. The syndrome of painful segmental spasms, spinal myoclonus, and rigidity, mentioned earlier, has also been observed under these conditions. It was presumed that vascular spasm and occlusion resulted in infarct necrosis. The frequency of this complication was greatly reduced by the introduction of less toxic contrast media.

**Treatment** The approach to all forms of spinal cord infarction is largely symptomatic, with attention during the acute stage to the care of bladder, bowel, and skin; after 10 to 14 days, more active rehabilitation measures can be started. Whether the acute effects of infarction can be modified by high-dose corticosteroids, agents that increase blood flow, or anticoagulation is not known. There are case reports of improvement in paraplegia following aortic dissection by the use of CSF drainage, as for example in the cases reported by Blacker and colleagues and by Killen et al, but other factors may have contributed.

**Hemorrhage of the Spinal Cord and Spinal Canal (Hematomyelia)**

Hemorrhage into the spinal cord is rare compared with the frequency of cerebral hemorrhage. The apoplectic onset of symptoms that involve tracts (motor, sensory, or both) in the spinal cord, associated with blood and xanthochromia in the spinal fluid, are the identifying features of hematomyelia. Aside from trauma, hematomyelia is usually traceable to a vascular malformation or a bleeding disease and particularly to the administration of anticoagulants. Actually, most vascular malformations of the spinal cord do not cause hemorrhage, but instead produce a progressive, presumably ischemic myelopathy, as described later and mentioned in the earlier section on necrotic myelopathy.

The same causes (anticoagulation, blood dyscrasia with coagulopathy, and AVM) may underlie bleeding into the epidural or subdural space (page 1072) and give rise to a rapidly evolving compressive myelopathy. In some cases, as in those of Leech and coworkers, one cannot ascertain the source of the bleeding, even at autopsy. Epidural or subdural bleeding, like epidural abscess, represents a neurologic emergency and calls for immediate radiologic localization and, in most cases, surgical evacuation.

Advances in the techniques of selective spinal angiography and microsurgery have permitted the visualization and treatment of vascular lesions that cause bleeding with a precision not imaginable a few decades ago. These angiographic procedures make it possible to distinguish among the several types of vascular malformations, arteriovenous fistulas, and vascular tumors such as hemangioblastomas and to localize them accurately to the spinal cord, epidural or subdural space, or vertebral bodies. This subject is discussed further on.

**Vascular Malformations of the Spinal Cord and Overlying Dura**

These are well-known lesions, occurring not infrequently and causing both ischemic and hemorrhagic lesions. Some are true arteriovenous malformations (AVM) and others more limited fistulas, mainly in the dura, the distinctions being the size of the nidus of communication between an artery and a vein and the size and location of feeding and draining vessels. The classification of spinal AVMs has been confusing, in part because the enlarged draining veins by which the lesions were formerly identified are probably a secondary feature. The most useful categorization reflects the appearance and location of the malformation by angiography and by surgical examination. These malformations may be divided into three groups: (1) arteriovenous malformations that are strictly intradural or also involve the meninges and surrounding structures such as the vertebral bodies to a limited extent; (2) a variety of intradural perimedullary fistulas that lie on the subpial surface of the cord (these probably conform most closely to the lesion described by Foix and Alajouanine discussed in the earlier section on necrotic myelopathy); and (3) purely dural fistulas. There is not sufficient pathologic material to determine whether these represent distinct pathologic entities or simply differing degrees and configurations of a common developmental process. Once recognized, treatment may be an urgent matter in cases with rapid clinical deterioration and impending paralysis.

**Dural Fistula** The last of the above listed malformations, spinal dural fistula, while not the classic AVM, is addressed first since it has emerged as the most common type in our practices. Increasingly, it has been recognized that arteriovenous fistulas that lie within the dura overlying the spinal cord, are capable of causing a myelopathy, sometimes several segments distant from the vascular nidus. The majority are situated in the region of the low thoracic cord or the conus, with a limited venous draining system. Some appear to be situated in a dural root sleeve and to drain into the normal perimedullary coronal venous plexus.

The presenting clinical features in our patients have included slowly progressive bilateral but asymmetric leg weakness with variable sensory loss. According to Jellema and colleagues who studied 80 patients with spinal dural fistulas, the most common initial symptoms were gait imbalance, numbness, and paresthesias. As the process progressed, the majority developed urinary problems, leg weakness, and numbness in the legs and buttocks. The degree of leg weakness varied greatly and back pain was infrequent.

The myelopathy that results is subacute or saltatory in evolution, presumably from venous congestion within the cord. A clau-dicatory syndrome has also been reported. Characteristically, activities that increase venous pressure (Valsalva maneuver, exercise) transiently amplify the symptoms or produce irreversible, stepwise worsening. One remarkable such case involved a baritone opera singer whose legs gave way repeatedly while singing (Khurana et al). As mentioned, some cases are painless, although most of our patients have had a moderate spinal ache or sciatica. In contrast to the classic arteriovenous lesions, these bleed only rarely. The spinal fluid is normal or shows a slight elevation of protein.

**Intradural AVM** The true AVM, previously referred to as angioma racemosum venosum or dorsal extramedullary arteriovenous malformation, is typically located on the dorsal surface of the lower half of the spinal cord and occurs most often in middle-aged and elderly men (23 of 25 of Logue’s patients were male). However, this lesion may occur at any age and at any location in the cord. In a few cases there has been an overlying dermatomal nevus. The clinical picture has been well described by Wyburn-Mason. Acute cramp-like, lancinating pain, sometimes in a sciatic distribution, is often a prominent early feature. It may occur in a series of episodes over a period of several days or weeks; sometimes it is worse in recumbency. Almost always it is associated with weakness or paralysis of one or both legs and numbness and paresthesias in the same distribution. Wasting and weakness of the legs may introduce the disease in some instances, with uneven progression, sometimes in a series of abrupt episodes. Severe disability
of gait is usually present within 6 months, and half of the patients described by Aminoff and Logue were chairbound within 3 years; the average survival in the past was 5 to 6 years, but the disorder has rarely been fatal in our patients. These lesions only infrequently give rise to intramedullary or subarachnoid hemorrhage. The spinal fluid shows high protein but little or no cellular reaction.

When viewed directly, the dorsal surface of the lower cord may be covered with a tangle of veins, some involving roots and penetrating the surface of the cord. The progression of symptoms is due presumably to the chronic venous hypertension and secondary intramedullary ischemic changes, and the abrupt episodes of worsening have been attributed to the thrombosis of vessels all on uncertain grounds. However, angiographic studies sometimes show only a single or a few such dilated draining vessels. Furthermore, there is not sufficient pathologic material to determine whether some of the more prominent venous anomalies represent true venous angiommas (probably they do not). As mentioned, these lesions rarely bleed.

Intradural Perimedullary and Subpial AVM The pial fistulous arteriovenous communication that involves the superficial aspect of the cord to a variable extent is the least frequent but probably of a similar nature to the dural type, or it may be related to the vascular lesion in the earlier mentioned Foix-Alajouanine process. In contrast to dorsal arteriovenous malformations, these fistulas tend to involve the lower thoracic and upper lumbar segments or the anterior parts of the cervical enlargement. The patients are often younger, and the sexes are equally affected. The clinical syndrome may take the form of slow spinal cord compression, sometimes with a sudden exacerbation; or the initial symptoms may be apoplectic in nature, due to either thrombosis of a vessel or a hemorrhage from an associated draining vein that dilates to aneurysmal size and bleeds into the subarachnoid space or cord (hematomyelia and subarachnoid hemorrhage); the latter complication occurred in 7 of 30 cases reported by Wyburn-Mason.

**Diagnosis** Any of these lesions, dural or intradural, may be revealed on CT myelography or MRI by the presence of one or more fortuitously discovered enlarged and serpiginous draining vessels in the subarachnoid space; just as often, they are not visualized by these methods (Jones et al). Other features that have been emphasized include enlargement of the spinal cord at the level of the lesion and, particularly in the case of spinal dural fistulas, with venous congestion and T2-bright enhancement of the swollen cord over several segments. Because of the low-flow nature of the vascular lesion, the same region may be T1 hypointense. Some clinicians have commented on the presence of peripherally located regions of T2-hypointense signal changes (Hurst and Grossman). Many of these changes reverse with appropriate surgical or radiological interventions that ablate the malformations.

The diagnosis is established through selective angiography, which shows the fistula in the dura overlying the cord or on the surface of the cord itself, but the most conspicuous finding is often the associated early draining vein (Fig. 44-8). As with other spinal cord malformations, demonstration of the fistula requires the painstaking injection of feeding vessels at numerous levels above and below the suspected lesion, since the main vessel of origin is often some distance away from the malformation. Also, blood flow through the nidus may be so rapid and brief that it is missed. In rare instances the fistula or high-flow arteriovenous malformation lies well outside the cord—for example, in the kidney—and gives rise to a similar myelopathy, presumably by raising venous pressures within the cord.

**Other Rare Vascular Anomalies of the Cord** In the Klippel-Trenaunay-Weber syndrome, a vascular malformation of the spinal cord is associated with a cutaneous vascular nevus; when the malformation lies in the low cervical region, there may be enlargement of finger, hand, or arm (the hemangiectatic hypertrophy of Parkes Weber; neurofibromatosis is another cause of limb enlargement). Spinal segmental and tract lesions may occur at any age, but three of our patients were young adults. Vascular occlusion or hemorrhage was responsible for the myelopathy. Some of these vascular lesions have been treated by defining and ligation of their feeding vessels. In a few reported cases it has been possible to extirpate the entire lesion, especially if it occupied the surface of the cord.

Other rare vascular anomalies of the spinal cord include aneurysm of a spinal artery with coarctation of the aorta and telangiectasia of the cord, which may or may not be associated with the hereditary hemorrhagic type of Osler-Rendu-Weber. The authors have had under their care over the years patients with the latter disease who developed acute hemorrhagic lesions of the spinal cord. Also, we have observed several cavernous hemangiomas of the spinal cord. In two of our cases, an angiographically negative solitary cavernous angioma had been the source of an acute partial transverse myelopathy. The lesions were clearly demonstrable only in the T2-weighted MR images. McCormick and associates have reported similar cases. Characteristically, the cord lesions cause partial syndromes and are followed by considerable recovery of function just as when they occur in the brain. There may or may not be blood in the CSF. Rarely, the same disease is responsible for one or more hemorrhagic lesions of the brain. The association of cavernous angiomas with arteriovenous fistulas of the lung is a rare finding, and the latter may be a source of brain abscess. In coarctation of the aorta, the circulation to the lower part of the spinal cord may be deficient, with resultant paresis of the legs, sensory loss, and sphincteric impairment. Or there may be intra-
cranial subarachnoid hemorrhage from a ruptured saccular aneurysm.

Treatment The rate of progression of the myelopathy from these various lesions varies greatly. In some cases, as already noted, it may become a matter of some urgency to reverse the venous congestion and avoid infarction of the cord. Other lesions require a more measured approach. By occluding the feeding artery of a spinal AVM or fistula, which is often single, and eliminating the pressure in veins, the course of disease can be arrested and pain reduced (Symon et al). In most of our cases, there has been postoperative improvement in the neurologic deficit over a few weeks or months. In cases of the larger racemose AVMs, stripping the enlarged veins along the dorsal cord is no longer considered necessary and may be dangerous. Increasingly, one resorts to obliteration of a fistula or a reduction of the AVM by the use of endovascular techniques, using special catheters and various types of embolic particles. The procedure is long and painstaking, for the radiologist must identify and embolize all the feeding vessels of the malformation; general anesthesia is required in most cases. This approach has certain drawbacks; recanalization occurs in many instances, as does distal occlusion of the venous drainage system. For these reasons, surgical ligation of the arterial supply is still preferred as the initial procedure for larger AVMs. Some surgeons advise a staged approach in which the size of the malformation is first reduced by endovascular techniques thereby making the surgery less complicated. Intralumbar fistulas are usually treated solely by endovascular methods. Interventional radiologic techniques have also been used to advantage in the intramedullary malformations, either as the sole treatment or in combination with surgery. Focused radiation has been tried but the results are difficult to evaluate since most series are small.

Fibrocartilaginous Embolism

In 1961, Naiman and coworkers described the case of an adolescent boy who died of sudden paralysis after a fall in a seated position. Postmortem examination revealed extensive myelomalacia due to occlusions of numerous spinal vessels by emboli of nucleus pulposus material. Bots and colleagues encountered three cases in one year, and we regularly see one or two such cases each year. The clinical picture is essentially one of spinal apoplexy—the patient experiences the abrupt onset of pain in the back or neck, accompanied by the signs of a transverse cord lesion affecting all sensory, motor, and sphincteric functions and evolving over a period of a few minutes to an hour or more. Occasionally, the syndrome spares the posterior columns thus simulating an anterior spinal artery occlusion. The CSF is normal. As with other types of cord infarction, the changes may not appear on MRI for a day or more.

In some of the reported instances there was said to have been no excessive activity or spinal trauma preceding the spinal cord symptoms. However, this has not been true of our patients, most of whom had been participating in some strenuous activity but often earlier in the day rather than at the time of the paraplegia. Others had fallen and injured themselves on the day of the illness or on preceding days; a direct blow to the back during contact athletic sports was the antecedent event in several others and is the one most easily understandable as a cause.

At autopsy numerous small arteries and veins within the spinal cord are occluded by fibrocartilage, with necrosis of the spinal cord over one or two segments. A ruptured disc of the usual type was not found in these patients, but high-resolution radiographs in a few of them have exposed a discontinuity of the cortical bone of the vertebral body adjacent to a collapsed disc and herniation of disc tissue into a vertebral body (Tosi et al). The explanation suggested by Yoganandan and colleagues is that the high intravertebral pressure forces nucleus pulposus material into venules and arteries of the marrow of the vertebral body, and thence into the adjacent radicular vessels. This mechanism has probably been overlooked in many cases of acute ischemic myelopathy.

Caisson Disease (Decompression Sickness, “the Bends”)

This extraordinary myelopathy is observed in persons who are subjected to high underwater pressure and then ascend too rapidly. It affects mainly the upper thoracic spinal cord as a result of nitrogen bubbles that form and are trapped in spinal vessels. There may be little or no involvement of the brain. Haymaker, who has provided the most complete account of the neuropathologic changes, observed ischemic lesions mainly in the white matter of the upper thoracic cord; the posterior columns were more affected than lateral and anterior ones. We have encountered instances in which an almost complete transverse myelopathy was evident soon after the patient resurfaced but then improved, leaving the patient with an asymmetrical and incomplete, albeit permanent, deficit. The smallest degree of damage is manifest as a minor myelopathy that affects the anterior or the posterior funiculi, leaving either spasticity or numbness of the legs. Immediate treatment consists of recompression in a hyperbaric chamber; later treatment is symptomatic, with antispasticity drugs and physical therapy.

Spinal Subdural Hemorrhage

This is an unusual process but we have had experience with a few cases that presented with exacerbating thoracic back pain of such severity as to cause a bizarre, almost psychotic, reaction (Swann et al). The neck becomes slightly stiff and there may be a headache, suggesting subarachnoid hemorrhage. However, signs of a myelopathy do not appear, indicating that the bleeding is confined to the pliable subdural spaces surrounding the cord. Lumbar puncture yields a distinctive dark yellow-brown spinal fluid that resembles crank case oil (in two of our cases). The color is imparted by methemoglobin and reflects the presence of adjacent, walled-off blood. Usually there are also red blood cells in the CSF, suggesting seepage into the subarachnoid space from the adjacent clot. MRI or CT myelography shows a subdural collection, with characteristically smooth borders. When drained operatively, this is found to be clotted blood. Usually, no vascular malformation is demonstrable and the cause remains obscure. Trauma or anticoagulation underlie a few cases but many are spontaneous. The symptoms resolve in 1 or 2 weeks after removal of the subdural hematoma. Small collections may be managed without surgery, in which case corticosteroids may be helpful in reducing the pain.

The syndrome of spinal subarachnoid hemorrhage has been mentioned earlier and is also covered on page 728.

THE SYNDROME OF SUBACUTE OR CHRONIC SPINAL PARAPARESIS WITH OR WITHOUT ATAXIA

The gradual development of weakness of the legs is the common manifestation of several diseases of the spinal cord. A syndrome of this type—including ataxia of gait beginning insidiously in late
childhood or adolescence and progressing steadily—is usually indicative of hereditary spinocerebellar degeneration (Friedreich ataxia) or one of its variants (see Chap. 39). In early adult life, MS is the most frequent cause and AIDS myelopathy is being increasingly recognized; syphilitic meningomyelitis, formerly of great importance, is now quite uncommon. In middle and late adult life, cervical spondylosis, subacute combined degeneration of the cord (vitamin B₁₂ deficiency), combined system degeneration of the nonpenniculous anemia type, radiation myelopathy, tropical spastic paraplegia, spinal arachnoiditis, and thoracic spinal tumor, particularly meningioma, are the other important diagnostic considerations for a slowly progressive syndrome. In most forms of subacute and chronic spinal cord disease, spastic paraparesis is more prominent than posterior column ataxia, Friedreich ataxia and myelopathy due to vitamin B₁₂ deficiency being notable exceptions.

**Spinal Multiple Sclerosis** (See earlier under “Demyelinating Myelitis”; also Chap. 36)

Ataxic paraparesis is among the most common manifestations of MS. Asymmetrical involvement of the limbs and signs of cerebral, optic nerve, brainstem, and cerebellar involvement usually provide confirmatory diagnostic evidence. Nevertheless, purely spinal involvement may occur, no lesions being found outside the spinal cord even at autopsy. A frequent problem in diagnosis is posed by the older adult patient who was not known to have had MS in earlier life, previous episodes having been asymptomatic or forgotten. The secondary progressive stage of the disease in this group appears to be the consequence of recurrent demyelinating attacks. There is another group, however, in which slowly advancing neurologic deterioration represents the primary manifestation of the disease. The National Hospital Research Group examined 20 cases of the secondary progressive type of spinal MS and 20 of the primary type by gadolinium-enhanced MRI of the spinal cord and brain and found new lesions in only 3 of each group (Kidd et al). They have suggested that the progression correlates better with progressive atrophy of the spinal cord than with recurrent demyelinating lesions. The clinical state must be differentiated from cervical disc disease, spondylosis, and tumor. As previously discussed, the main aids in diagnosis are the CSF findings (minor pleocytosis and oligoclonal IgG abnormalities), present in 70 to 90 percent of cases, the demonstration by evoked potential studies of lesions in the optic nerves or in the auditory and sensory tracts, and by MRI, which may disclose other unsuspected white matter lesions in the spinal cord and brain.

**Cervical Spondylosis with Myelopathy**

It has been stated, correctly in our opinion, that this is the most frequently observed myelopathy in general practice. Basically a degenerative disease of the spine involving the lower and midcervical vertebrae, it narrows the spinal canal and intervertebral foramina and causes progressive injury of the spinal cord, roots, or both.

**Historical Note** Key, in 1838, probably gave the first description of a so-called spondylotic bar. In two cases of compressive myelopathy with paraplegia, he found “a projection of the intervertebral substance and posterior ligament of the spine, which was thickened and presented as a firm ridge which had lessened the diameter of the canal by nearly a third. The ligament, where it passes over the posterior surface of the intervertebral substance, was found to be ossified.” In 1892, Horsley performed a cervical laminectomy on such a patient, removing a “transverse ridge of bone” compressing the spinal cord at the level of the sixth cervical vertebra. Thereafter, operations were performed in many cases of this sort, and the tissues removed at operation were repeatedly misidentified as benign cartilaginous tumors or “chondroma.” In 1928, Stookey described in detail the pathologic effects upon the spinal cord and roots of these “ventral extradural chondromas.” Feet and Echols, in 1934, were probably the first to suggest that the so-called chondromata represented protrusions of intervertebral disc material. But this idea never gained wide credence until the publication, in the same year, of the classic article on ruptured intervertebral disc by Mixter and Barr. Although their names are usually associated with the lumbar disc syndrome, 4 of their original 19 cases were instances of cervical disc disease. It was C. S. Kubik who identified the nucleus pulposis from surgical specimens obtained by Mixter and Barr’s cases.

Also of historical importance is Gowers’s account, in 1892, of vertebral exostoses, in which he described osteophytes that protrude from the posterior surfaces of the vertebral bodies and encroach upon the spinal canal, causing slow compression of the cord as well as bony overgrowth in the intervertebral foramina, giving rise to radicular pain. Gowers correctly predicted that these lesions would offer a more promising field for the surgeon than would other kinds of vertebral tumors.

For some reason, there was little awareness of the frequency and importance of spondylotic myelopathy for many years after these early observations had been made. All the interest was in the acute ruptured disc. Finally, it was Russell Brain, in 1948, who put cervical spondylosis on the neurologic map, so to speak. He drew a distinction between acute rupture and protrusion of the cervical disc (often traumatic and more likely to compress the nerve roots than the spinal cord) and chronic spinal cord and root compression consequent upon disc degeneration and associated osteophytic outgrowths (hard disc) as well as changes in the surrounding joints and ligaments. In 1957, Payne and Spillane documented the importance of a developmentally smaller-than-normal spinal canal in the genesis of myelopathy in patients with cervical spondylosis. These reports were followed by a spate of articles on the subject (see Wilkinson). Rowland’s review of the natural history of cervical spondylosis and the results of surgical therapy is a useful modern reference, as is that of Uttley and Monro.

**Symptomatology** The characteristic syndrome consists of varying combinations of the following: (1) painful, stiff neck or pain in the neck, shoulders, and upper arms (brachialgia) that may be aching or radicular (stabs of sharp and radiating pain evoked by movement); asymmetric or unilateral; (2) numbness and paresthesias mainly of the hands; and (3) spastic leg weakness with Babinski signs, unsteadiness of gait, and a Romberg sign. The numbness and paresthesias are occasionally the earliest symptoms and typically involve the distal limbs, especially the hands. Variations of these symptoms are elaborated later. Each of the components may occur separately, or they may occur in several combinations and sequences.

With reference to the most common of these symptoms, the neck and shoulder pain, in any sizable group of patients beyond 50 years of age, about 40 percent will be found at times to have some clinical abnormality of the neck, usually crepitus or pain, with restriction of lateral flexion and rotation (less often of extension). Pallis and colleagues, in a survey of 50 patients, all of them over 50 years of age and none with neurologic complaints, found that 75 percent showed radiologic evidence of narrowing of the cervical
spinal canal due to osteophytosis of the posterior vertebral bodies or to narrowing of the intervertebral foramina due to osteoarthropathy at the apophyseal joints; thickening of the ligaments (both the ligamentum flavum posteriorly and the posterior longitudinal ligament anteriorly) adds to the narrowing of the canal. However, only half of the patients with radiologic abnormalities showed physical signs of root or cord involvement (changes in the tendon reflexes in the arms, briskness of reflexes and impairment of vibratory sense in the legs, and sometimes Babinski signs). The occasional finding of a Babinski sign in older individuals who had never had a stroke or complained of neurologic symptoms is often explained by an otherwise invident cervical osteophyte (Savitsky and Madonick).

The pain is usually centered at the base of the neck or higher, often radiating to an area above the scapula. When brachialgia is also present, it takes several forms: a sharp pain in the pre- or postaxial border of the limb, extending to the elbow, wrist, or fingers; or a persistent dull ache in the forearm or wrist, sometimes with a burning sensation. Discomfort may be elicited by coughing, Valsalva maneuver, or neck extension, or neck flexion may induce electrical feelings down the spine (Lhermitte symptom). Rarely, the pain is referred substernally.

As to the sensory disorders (which may occasionally be absent), numbness, tingling, and prickling of the hands and soles of the feet and around the ankles are the most frequent complaints. Some patients complain of numbness or paresthesias, most often in one or two digits, a part of the palm, or a longitudinal band along the forearm. Slight clumsiness or weakness of a hand is another complaint. A feeling as if “wearing gloves,” “swollen,” or the hands “coated with glue” are common descriptions. Several of our patients complained of paresthesias in the distal limbs and trunk for months before there was any indication of motor involvement. In advanced cases there may be a vague sensory level at or just above the clavicles. Impaired vibratory sensation and diminished position sense in the toes and feet (all indicative of a lesion of the posterior columns) as well as the Romberg sign are the most conspicuous sensory findings. This imparts a “tabetic” unsteadiness to the gait in advanced cases. These sensory defects tend also to be asymmetrical (it is noteworthy that symmetric sensory symptoms and signs of identical type are seen with subacute combined degeneration due to $B_{12}$ deficiency.) Rarely, the sensorimotor pattern takes the form of a Brown-Séquard syndrome. Less frequently, paresthesias and dysesthesias in the lower extremities and trunk may be the principal symptoms; even less often there are sensory complaints on the face, ostensibly corresponding to compression of the trigeminal sensory tract in the upper cervical cord.

The third part of the typical syndrome, spastic legs from a compressive myelopathy, most often presents as a complaint of weakness of a leg and slight unsteadiness of gait. The whole leg or the quadriceps feels stiff and heavy and gives out quickly after exercise. Mobility of the ankle may be reduced, and the advancing toe of the shoe scrapes the floor. On examination, hypertonicity is more evident than weakness, and the tendon reflexes are increased (ankle jerks may not share in this change in the elderly). Although the patient may believe that only one leg is affected, it is commonly found that both plantar reflexes are extensor, the one on the side of the stiffer leg being more clearly so. Less often both legs are equally affected. As the compression continues, walking becomes unsteady because of the addition of sensory ataxia.

The biceps and brachioradial reflexes on one or both sides may be depressed, sometimes in association with an increase in the triceps and finger reflexes. The hand or forearm muscles, may undergo slight atrophy, in a few cases, the atrophy of hand muscles is severe. Interestingly, in such cases, the spondylotic compression, as judged by MRI or CT myelography, may be confined to the high cervical cord, well above the levels of the motor neurons that innervate these muscles. In patients with sensory loss, pain and thermal sensation often appear to be affected more than tactile sense. An unexpected Babinski sign has already been mentioned and a few fasciculations may be seen, especially in proximal muscles.

As the myelopathy progresses, sometimes intermittently, both legs become weaker and more spastic. Sphincteric control may then be altered; slight hesitancy or precipitancy of micturition are the usual complaints; frank incontinence is infrequent. In the more advanced form of this condition, walking requires the aid of a cane or canes or a walker; in some cases all locomotion ultimately becomes impossible, especially in the elderly patient. Abrupt worsening, even paraplegia or quadriplegia, may follow forceful flexion or extension injuries of the neck, as indicated later.

**Pathologic Changes** The fundamental lesion is generated initially by a fraying of the annulus fibrosus, with extrusion of disc material into the spinal canal. The disc becomes covered with fibrous tissue or partly calcified, thereby forming a transverse osteophytic “spondylotic bar” or there may be simply central bulging of the annulus without extrusion of nuclear material. The latter changes, unlike ruptured discs that occur mainly at the C5-6 or C6-7 interspace, often involve higher interspaces and almost invariably occur at several adjacent levels. The dura mater may be thickened and adherent to the posterior longitudinal ligament at affected levels. The underlying pia-arachnoid is also thickened and the adjacent ligamentous hypertrophy contributes to compression of the cord or the nerve roots. This series of pathologic changes is often ascribed to hypertrophic osteoarthritis. However, in lesser degree, the osteophyte formation and ridging are so frequently observed in patients who have no other signs of arthritic disease that this explanation is surely not totally correct. Subclinical trauma is far more likely to be the cause of spondylotic bar formation, in the authors’ opinion.

When a cervical nerve root is compressed by lateral osteophytic overgrowth, the dural sleeve is thickened and occluded and the root fibers are damaged. Usually the fifth, sixth, or seventh cervical roots are affected in this way, both the anterior and posterior or only the anterior, on one or both sides. A small neuroma may rarely appear proximal to the site of anterior root compression. The dura is ridged and the underlying spinal cord is flattened. The root lesions may lead to secondary wedge-shaped areas of degeneration in the lateral parts of the posterior columns at higher levels. The most marked changes in the spinal cord are at the level(s) of compression. There may be zones of demyelination or focal necrosis at the points of attachment of the dentate ligaments (which tether the spinal cord to the dura) and areas of rarefaction in the posterior and lateral columns as well as loss of nerve cells. Ventral gray matter lesions, often asymmetrical, are attributed by Hughes to ischemia.

**Pathogenesis** The particular vulnerability of the cervical spine to degenerative change has no ready explanation. Most likely it is related in some way to the high degree of mobility of the lower cervical vertebrae, which is accentuated by their location next to the relatively immobile thoracic spine.

The mechanism of spinal cord injury would seem to be one of simple compression and ischemia as mentioned. When the spinal
canal is diminished in its anteroposterior dimension at one or several points, the space available for the spinal cord becomes insufficient. A developmentally small canal (reduced anteroposterior diameter) certainly makes an individual subject to the compressive effects of spondylosis. The range of narrowing of the canal that produces symptomatic cervical spondylosis is generally from 7 to 12 mm (normal canal diameter, 17 to 18 mm). One must consider, therefore, several additional mechanisms by which the cord might be damaged. The effects of the natural motions of the spinal cord during flexion and extension of the neck are probably important in this respect. Adams and Logue confirmed the observation of O’Connell that, during full flexion and extension of the neck, the cervical cord and dura move up and down. The spinal cord is literally dragged over protruding osteophytes and hypertrophied ligaments; conceivably it is this type of intermittent trauma that causes progressive injury. It has also been shown that the spinal cord, displaced posteriorly by osteophytes, is compressed by the infolding of the posterolateral ligamentum flavum each time the neck is extended (Stoltmann and Blackwood). Segmental ischemic necrosis resulting from intermittent compression of spinal arteries or from compression of the anterior spinal artery has also been postulated. Most neuropathologists favor the idea of intermittent cord compression between osteophytes anteriorly and ligamentum flavum posteriorly, with an added vascular element accounting for the scattered lesions deep in the cord. Trauma from sudden extreme extension, as in a fall, severe whiplash injury, or chiropractic manipulation, or from a lesser degree of retraction of the head during myelography, tooth extraction, or a tonsillectomy may be operative in individual cases, particularly in patients with congenitally narrow canals. The lateral extension of the osteophyte and hypertrophy of the facet joint together compress the nerve root as it is entering its spinal foramen. Sometimes these are the main changes and cause only a radiculopathy, as discussed in Chap. 11.

Diagnosis When pain and stiffness in the neck, brachialgia, either in the form of aching or a more distinctive radicular pain, and sensorimotor-reflex changes in the arms are combined with signs of myelopathy, there is little difficulty in diagnosis. When the neck and arm changes are inconspicuous or absent, the diagnosis becomes more difficult. The myelopathy must then be distinguished from the late, progressive form of spinal MS. Since posterior vertebral osteophytes and other bony alterations are frequent in the sixth and seventh decades, the question that must be answered in any given case is whether the vertebral changes are related to the neurologic abnormality. The finding of some degree of sensorimotor or reflex change corresponding only to the level of the spinal abnormalities is a point that favors spondylotic myelopathy. A lack of such corresponding changes and the presence of oligoclonal bands and signs of lesions in the optic nerves and brain indicate demyelinative myelopathy.

The findings on both MRI and CT myelography become critical in such cases (Fig. 44-9). The MRI tends to overestimate the degree of cord compression by an osteophyte, but clear deformation of the cord into the shape of a bean and obliteration of the surrounding CSF spaces in the transverse image support the diagnosis of spondylotic compression. Signal changes within the body of the cord are seen in advanced cases and usually indicate a degree of irreversibility of at least the sensory symptoms. Curiously, these signal changes may be one or two levels above or below the site of main compression. However, serious and reversible symptoms may occur even without intrinsic changes in the MRI signal. Contrast myelography with the patient supine and lateral views taken during flexion and extension of the neck are useful diagnostic procedures in uncertain cases. To confidently attribute neurologic symptoms to spondylosis there should be flattening of the cord and considerable encroachment on the CSF space at that level, not simply an impingement or slight deformation of the normal oval shape of the cord.

It has been said that spondylotic myelopathy may simulate amyotrophic lateral sclerosis (amyotrophy of arms and spastic weakness of the legs). This has seldom been a diagnostic problem. While brachial and shoulder fasciculations with muscle atrophy may be combined with hyperreflexia in spondylosis, the widespread denervation and progressive course of ALS is not in evidence. We have observed only a few patients with spondylotic myelopathy who exhibited an absolutely pure motor syndrome, i.e., one in which there was no cervical or brachial pain and no sensory symptoms in the arms or impairment of vibratory or position sense in the legs. Likewise, a pure spastic paraparesis is more likely to be a manifestation of MS, hereditary spastic paraplegia, motor neuron...
disease (primary lateral sclerosis type), HTLV-I myelopathy, or the carrier state of adrenoleukodystrophy or other intrinsic myelopathy.

When imbalance, both perceived by the patient and observed in tests of walking, is a major symptom, spondylitis must be differentiated from a number of acquired large-fiber polyneuropathies, particularly inflammatory or immune types and the more benign sensory neuropathy of the aged (see page 1151). Loss of tactile sensation in the feet and loss of tendon reflexes are characteristic of the latter; examination of the tendon reflexes distinguishes the two. Subacute combined degeneration of the spinal cord due to vitamin B₁₂ deficiency, combined system disease of the nonpenicillous anemia type, AIDS and HTLV-I myelopathy, ossification of the posterior longitudinal ligament, and spinal cord tumor (discussed further on) are usually listed among the conditions that might be confused with spondylotic myelopathy. Adherence to the diagnostic criteria for each of these disorders and scrutiny of the radiologic studies should eliminate the possibility of error in most instances. The gait abnormality produced by spondylotic myelopathy may also be mistaken for that of normal-pressure hydrocephalus; a marked increase of imbalance with removal of visual cues (Romberg sign) is a feature of spondylitis but not of hydrocephalus. Also, the short stepped and magnetic quality of walking that is characteristic of hydrocephalus is not seen in cases of cervical myelopathy. Incontinence occurs only in advanced cases of spondylotic myelopathy, but usually follows soon after gait deterioration in hydrocephalus.

The special problems of spondylotic radiculopathy, which may accompany or occur independently of the myelopathy, are discussed on pages 184 and 186.

**Treatment** The slow, intermittently progressive course of cervical myelopathy with long periods of relatively unchanging symptomatology makes it difficult to evaluate therapy. Assuming that the prevailing opinion of the mechanisms of the cord and root injury is correct, the use of a soft collar to restrict anteroposterior motions of the neck seems reasonable. This form of treatment alone may be sufficient to control the discomfort in the neck and arms. Only exceptionally in our experience has arm and shoulder pain alone been sufficiently severe and persistent to require surgical decompression unless there is a laterally protruded disc or osteophytic constriction of a root foramen.

Most of our patients have been dissatisfied with this passive approach and are unable to wear a collar for prolonged periods. If osteophytes have narrowed the spinal canal at several interspaces, a posterior decompressive laminectomy with severance of the denticate ligaments helps to prevent further injury. The results of such a procedure are fairly satisfactory (Epstein and Epstein); in fully two-thirds of the patients, improvement in the function of the legs occurs, and in most of the others, progression of the myelopathy is halted. The operation carries some risk; rarely, an acute quadriplegia—due presumably to manipulation of the spinal cord and damage to nutrient spinal arteries—has followed the surgical procedure. When only one or two interspaces are the site of osteophytic overgrowths, their removal by an anterior approach has given better results and carries less risk. The surgical methods and their relative advantages are reviewed by Braakman. Newer techniques have been developed in which titanium cages are used to stabilize the adjacent vertebrae thereby obviating the need for bone grafts to fuse adjacent bodies; the conventional process using bone grafts requires many weeks or longer and stabilization in a hard collar.

Unfortunately, the long-term results after surgical treatment are less than ideal. Ebersold and colleagues evaluated the outcomes in 84 patients in whom the median duration of follow-up was 7 years. In the group of 33 patients who had undergone anterior decompressive procedures, 18 had improved, 9 were unchanged, and 6 had deteriorated. Of the 51 patients who underwent posterior decompression, 19 had improved, 13 were unchanged, and 19 were worse at their last follow-up examinations. These results, similar to those of most other series, indicate that the long-term outcome varies and that a significant proportion, even after adequate decompression and initial improvement, have persistent symptoms or undergo some degree of later functional deterioration. Whether the new surgical appliances previously mentioned give more satisfactory results is not known but they certainly make recovery easier and more rapid.

**Lumbar Stenosis** This is another spondylotic abnormality, seen with particular frequency in older individuals, especially men. Usually it declares itself by numbness and weakness of the legs, sometime with poor control of sphincters. There is said to be generally little or no pain or only a spine ache that fluctuates from day to day but in our experience the majority of patients have backache and sciatica or a similar back or leg pain from associated osteoarthritis or discogenic disease. A notable feature is induction or aggravation of the neurologic symptoms upon standing and walking (neurologic claudication). This topic is discussed further on page 179, which should be consulted for further discussion.
